CHAPTER 24

Heart Failure

Yazid N. Al Hamarneh and Ross T. Tsuyuki

Heart failure is a major cause of morbidity and mortality in Western society.[1-4] It is one of the most common reasons for hospitalization, with over 5 million hospitalizations per year in the United States and 106,000 per year in Canada.[4,5] The duration of stay for patients hospitalized with heart failure is long, averaging about 13 days, and in-hospital mortality is high, between 3.2 and 15%.[4,6]

Coronary artery disease is by far the most common cause of heart failure in the United States, accounting for approximately two thirds of cases.[7] Other causes include hypertension, myocarditis, and cardiac toxins, including drugs, which can cause or exacerbate a stable pattern of heart failure.[7,8] Drug-induced heart failure in patients without pre-existing left ventricular dysfunction is quite rare, and drug-induced exacerbation of symptoms of heart failure occurs more frequently in those with established heart failure.[9] This chapter will focus on drug-induced heart failure, primarily heart failure with reduced ejection fraction (HFrEF), including causative agents, epidemiology, mechanism of action, and clinical presentation.

CAUSATIVE AGENTS

Left ventricular ejection fraction (LVEF), also simply referred to as ejection fraction (EF), is used as the primary term to define heart failure.[10] Based on LVEF, heart failure can be divided into heart failure with reduced ejection fraction (HFrEF) if EF is <40% or heart failure with preserved ejection fraction (HFpEF) if the EF is >50%.[10,11]

The agents implicated in drug-induced heart failure are listed in **Table 24-1**.[12-109] Causality is often difficult to ascertain because of the multiplicity of factors that can exacerbate heart failure symptoms. Most calcium-channel blockers (except felodipine and amlodipine), antihyperglycemic agents (dipeptidyl peptidase 4 [DPP-4] inhibitors and thiazolidinediones [“glitazones”: rosiglitazone and pioglitazone]), antiarrhythmic agents, anthracyclines (doxorubicin), biologics (bevacizumab, infliximab, lapatinib, trastuzumab), nonsteroidal anti-inflammatory agents (NSAIDs), selective cyclooxygenase-2 (COX-2) inhibitors, and adrenergic β-receptor antagonists (β-blockers) have all been implicated in drug-induced heart failure.

Table 24-1 Agents Implicated in Drug-Induced Heart Failure

Drug	Incidence	Level of Evidence[a]
α_1-antagonists		
Doxazosin[12]	RR 2.04, 95% CI 1.79–2.32	A
Amantadine[13]	NK	C
Aminocaproic acid[14]	NK	C
Amphotericin B[15,16]	NK	C

Sunitinib[191]	NK	B
Tricyclic antidepressants[104-107]	NK	C
Imipramine	NK	C
Amitriptyline	NK	C
Protriptyline	NK	C
Nortriptyline	NK	C
Clomipramine	NK	C
Venlafaxine[108]	NK	C
Zidovudine[109]	NK	C

CI = confidence interval, COX = cyclooxygenase, DPP = dipeptidyl peptidase, HF = heart failure, HR = hazard ratio, LVEF = left ventricular ejection fraction, NK = not known, NSAID = nonsteroidal anti-inflammatory drug, NYHA = New York Heart Association, OR = odds ratio, PEG = polyethylene glycol, RR = relative risk.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials;

Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

Isolated case reports have identified other agents as possible causes of drug-induced heart failure (see Table 24-1 for details). Because causality related to these agents is much less certain, these will not be discussed in detail in this chapter. The reader is referred to a comprehensive review by Amabile and Spencer[110] that outlines medications to avoid in patients with heart failure and review papers by Feenstra et al.,[9] Slordal and Spigset,[111] and Maxwell and Jenkins[112] for further discussion of heart failure associated with these agents.

Although drug-induced heart failure in patients without pre-existing left ventricular dysfunction is relatively rare, drug-induced exacerbations of symptoms in those with pre-existing left ventricular dysfunction is more common. Drug-induced causes, expressed as a proportion of all heart-failure exacerbations, are shown in **Table 24-2**. In a prospective study of factors associated with acute exacerbation of heart failure, Tsuyuki et al.[113] reported on 323 episodes of worsening HFrEF in 180 patients during the 43 weeks of the Randomized Evaluation of Strategies for Left Ventricular Dysfunction (RESOLVD) pilot study. Although the most commonly identified precipitant of exacerbations of acute HFrEF was excessive salt intake (22%), antiarrhythmic agents, study medications (which were metoprolol and candesartan and/or enalapril administered in a blinded fashion), and calcium-channel blockers were all implicated. Interestingly, however, medications were not thought to be the primary cause of any of these exacerbations; rather, nonadherence to salt restrictions, followed by other noncardiac causes (such as upper respiratory tract infections), were the most common causes of excerbations.[113]

Table 24-2 Proportion of Heart Failure Exacerbations That Are Drug-Induced[a]

Study	Precipitating Agent(s)	Incidence
Tsuyuki et al.[113,b]	Antiarrhythmic agents	15%
	"Study medications" (β-blockers or placebo)	15%
	Calcium channel blockers	13%
	Nonstudy open-label β-blockers	9%
	NSAIDs	5%
Rich et al.[114]	Fluids (excessive intravascular volume expansion)	5.5%
	β-blockers	0.25%
	Verapamil	0.25%
Garcia Robles et al.[31]	β-blockers	2%

NSAID = nonsteroidal anti-inflammatory drug.

[a] Does not include underuse of drugs (i.e., discontinuation of therapy with diuretics).

[b] Categories not mutually exclusive.

In a review of 401 patients over the age of 70 years hospitalized with HFrEF or HFpEF (average LVEF was 52% in iatrogenic heart failure group and 44% in the noniatrogenic group), Rich et al.[114] determined that iatrogenic causes were present in 28 patients (7%). The most common cause was excessive intravascular volume expansion (22 patients) followed by administration of blood products (3 patients) or verapamil (1 patient).[114] In a review of 100 hospitalizations of patients over 65 years of age with HFrEF, Garcia Robles et al. identified two cases (2%) caused by β-blockers.[31] Other studies revealed acute angina, respiratory infection, uncontrolled hypertension, arrhythmias, and poor adherence to medication therapy as common precipitants of exacerbations of HFrEF and HFpEF.[113-117]

EPIDEMIOLOGY

The incidence of drug-induced heart failure (HFrEF, HFpEF, heart failure with unreported EF) is outlined in Table 24-1. The precise incidence of drug-induced heart failure is difficult to determine because it is often challenging to differentiate drug-induced heart failure from the many other precipitants of this syndrome.[113]

CALCIUM-CHANNEL BLOCKERS

In a post hoc analysis of the Multicentre Diltiazem Postinfarction Trial (MDPIT), Goldstein et al.[38] reported new or worsened HFrEF in 12% and 20.5% of 623 patients receiving placebo or diltiazem, respectively ($p = 0.004$). There was no difference in the incidence of new or worsened heart failure (in patients with LVEF > 0.40) at baseline, highlighting the significant hazard of diltiazem use in patients with left ventricular dysfunction after myocardial infarction.[38] In a randomized, double-blind crossover study of 8 weeks of treatment with isosorbide dinitrate alone, isosorbide dinitrate in combination with nifedipine, or nifedipine alone in 28 patients with mild-to-moderate HFrEF, there were higher incidences of hospitalization due to worsening heart failure in the isosorbide dinitrate plus nifedipine (26%) and nifedipine alone (24%) groups compared to that in the isosorbide dinitrate alone group (0%).[39]

In the second Prospective Randomized Amlodipine Survival Evaluation (PRAISE-2) study, 1,654 patients with HFrEF were randomized to receive amlodipine or placebo. The hazard ratio for death was 1.09 (95% CI 0.92–1.29), indicating no survival benefit (or adverse effect on survival) associated with amlodipine. Many have interpreted these results to mean that amlodipine can be used in patients with HFrEF who need it for reasons other than heart failure (e.g., hypertension or angina not controlled by other agents).[118] Similar recommendations have been made regarding felodipine based on the results of the third Vasodilators in Heart Failure Trial (V-HeFT III), in which patients with HFrEF were randomized to receive felodipine or placebo; there were no differences between the groups in mortality or hospitalization rates.[119]

ANTIHYPERGLYCEMIC AGENTS

GLITAZONES

The glitazone drugs are a well-known cause of fluid retention.[54,55,57,58] Tang et al.[55] reviewed the records of 111 consecutive patients with HFrEF and diabetes who were prescribed a glitazone agent and reported that the incidence of fluid retention was 17%. Of those who fulfilled the criteria for fluid retention, 26% were hospitalized to manage the condition and 11% had pulmonary edema. There was no difference in the baseline New York Heart Association (NYHA) functional heart failure class between patients who developed fluid retention and those who did not. In the randomized A Diabetes Outcome Progression Trial (ADOPT), a higher incidence of heart failure was reported in the rosiglitazone group compared to that in the glyburide group (HR 2.2, 95% CI 1.01–4.79, $p = 0.05$) though not compared to that in the metformin group (HR 1.22, 95% CI 0.66–2.26, $p = 0.52$).[120] A higher incidence of pulmonary edema and use of loop diuretics was also reported in the rosiglitazone group (14.1%) compared to that associated with glyburide (8.5%; $p < 0.001$) or metformin (7.2%; $p < 0.001$).[120]

More recently, several clinical trials and meta-analyses have investigated the impact of glitazone therapy on cardiovascular outcomes, including the incidence of heart failure. In the Diabetes Reduction Assessment with Ramipril and Rosiglitazone Medication (DREAM) study, 5,269 adults with impaired fasting glucose or impaired glucose tolerance or both and no previous cardiovascular disease were randomly assigned to receive rosiglitazone or placebo.[60] A higher proportion of patients in the rosiglitazone group developed heart failure than in the placebo group (0.5% versus 0.1%, respectively, $p = 0.01$). In the Rosiglitazone Evaluated for Cardiac Outcomes and Regulation of Glycemia (RECORD) study, 4,447 patients with inadequate glycemic control were randomly assigned to receive add-on rosiglitazone therapy or metformin plus sulfonylurea (control group). In an interim analysis, the hazard ratio for the development of heart failure associated with rosiglitazone was 2.15 (95% CI 1.30–3.57).[61] Pioglitazone has also been associated with an increased rate of heart failure. In the Prospective Pioglitazone Clinical Trial In Macrovascular Events (PROactive) study, 5,238 patients with type 2 diabetes and evidence of macrovascular disease were randomly assigned to receive pioglitazone or placebo. Pioglitazone was associated with a higher incidence of heart failure (11% versus 8%; $p < 0.0001$).[65] Several meta-analyses have also documented an increased incidence of heart failure (new cases and worsening symptoms) in patients receiving glitazones (Table 24-1).[59,62,63,66]

Notably, although both rosiglitazone and pioglitazone have been associated with an increased incidence of heart failure (new cases and worsening symptoms), to date only rosiglitazone has been shown to be associated with an increased risk of myocardial infarction (OR 1.43, 95% CI 1.03–1.98).[121] Neither rosiglitazone nor pioglitazone has been shown to increase the risk of cardiovascular mortality.[59,62,66] A joint consensus statement by the American Heart Association and the American Diabetes Association recommended cautious use of lower doses of glitazones in patients with NYHA functional class I–II symptoms and avoidance of these agents in those with NYHA class III–IV symptoms.[56] It is best to avoid glitazones in patients with heart failure, in view of the fact that there are many oral antihyperglycemic agents that can be used in this population.

DIPEPTIDYL PEPTIDASE (DPP)-4 INHIBITORS

In light of the latest evidence, the focus of many diabetes trials has shifted toward cardiovascular safety outcomes (rather than an expectation of reducing cardiovascular risk). Scirica et al.[122] conducted a multicenter, randomized, double-blind, placebo-controlled trial to assess the cardiovascular safety and efficacy of saxagliptin in patients with type 2 diabetes who had a history of established cardiovascular disease or multiple risk factors for vascular disease. There was no significant difference between the saxagliptin and placebo groups in the primary endpoint (composite of cardiovascular death, nonfatal myocardial infarction, or nonfatal ischemic stroke) (HR 1, 95% CI 0.89–1.12, $p = 0.99$) nor in the major secondary endpoints (composite of cardiovascular death, nonfatal myocardial infarction, nonfatal ischemic stroke, hospitalization for unstable angina, coronary revascularization, or heart failure (HR 1.02, 95% CI 0.94–1.11, $p = 0.66$). However, saxagliptin increased the risk of hospitalization for heart failure (HR 1.27, 95% CI 1.07–1.51, $p = 0.007$). White et al.[123] conducted a multicenter, randomized, double-blind noninferiority trial of the effects of alogliptin on major cardiovascular events in patients with type 2 diabetes who had an acute coronary syndrome within 15–90 days before randomization. Alogliptin did not increase the risk of hospitalization for heart failure (HR 1.19, 95% CI 0.89–1.59, $p = 0.24$). Green et al.[124] employed a similar design to assess the cardiovascular safety of sitagliptin versus placebo in patients with type 2 diabetes who had established cardiovascular disease. Sitagliptin did not increase the risk of cardiovascular death, nonfatal myocardial infarction, nonfatal stroke, or hospitalization for unstable angina (HR 0.98, 95% CI 0.8–1.08, $p = 0.65$) or the risk of hospitalization for heart failure (HR 1, 95% CI 0.83–1.20, $p = 0.98$). Weir et al.[125] assessed the effects of sitagliptin on patients with type 2 diabetes and heart failure in a population-based retrospective cohort study. When compared to metformin or a sulfonylurea, sitagliptin did not increase the risk of all-cause mortality and hospitalization (adjusted OR 0.84, 95% CI 0.69–1.03, $p = 0.10$). However patients who received sitagliptin were at higher risk of hospital admission due to heart failure (adjusted OR 1.84, 95% CI 1.16–2.92, $p = 0.01$).

ANTIARRHYTHMIC AGENTS

Ravid et al.[28] reviewed the incidence of drug-induced heart failure in 407 patients during 1,133 serial electrophysiologic drug tests with encainide, moricizine, lorcainide, mexiletine, propafenone, or tocainide. Using a strict definition of HFrEF, they reported an overall incidence of drug-induced heart failure of 1.8%. The incidence increased to 3.8% in patients with a history of heart failure. In this study, lorcainide (not available in the United States) was associated with the lowest incidence of heart failure (0.7%), while propafenone was associated with the highest incidence (4.7%). In a randomized, controlled trial investigating the impact of antiarrhythmic therapy postmyocardial infarction, Greene et al.[27] reported no significant difference in the proportion of patients who developed heart failure symptoms or diagnoses requiring hospitalization in patients receiving imipramine (which at the time was studied for possible antiarrhythmic effects), encainide, flecainide, or moricizine (26%) compared with those receiving placebo (18%).[27] Pfisterer estimated that the incidence of drug-induced heart failure associated with older antiarrhythmic agents (excluding ibutilide and dofetilide) is about 5% overall and approximately 10% in those with a history of heart failure.[29] Disopyramide has well-known negative inotropic effects, and flecainide has also been reported to worsen heart failure.[126,127]

Amiodarone, ibutilide, and dofetilide appear to exert minimal negative inotropic effects, and amiodarone and dofetilide are neutral with respect to survival in patients with heart failure.[1] Therefore, amiodarone and dofetilide are recommended for prevention of recurrent atrial fibrillation in patients with HFrEF.[1,2] In contrast, the Antiarrhythmic Trial with Dronedarone in Moderate to Severe CHF Evaluating Morbidity Decrease (ANDROMEDA) trial found that dronedarone, an antiarrhythmic drug with properties similar to those of amiodarone, was associated with increased early mortality related to the worsening of heart failure symptoms in patients who were hospitalized with symptomatic severe HFrEF.[30] During a median follow-up of 2 months, 8.1% of patients receiving dronedarone died, compared with 3.8% receiving placebo (HR 2.13, 95% CI 1.07–4.25, $p = 0.03$), and this excess mortality was predominantly related to worsening of heart failure (3.2% versus 0.6%; p value not reported). An increase in mortality associated with dronedarone was not observed in another trial in which patients with decompensated NYHA class IV HFrEF were excluded (no difference in all-cause mortality, and a reduction in death from cardiovascular causes—dronedarone, 2.7%, versus placebo, 3.9%; HR 0.71, 95% CI 0.51–0.98).[128] It is recommended that dronedarone should be avoided in patients with HFrEF.[129] Overall, heart failure is a known risk factor for proarrhythmic effects and most antiarrhythmic agents worsen heart failure symptoms. Risk versus benefit evaluation is extremely important in this patient population. Amiodarone and dofetilide appear to be the antiarrythmic agents that are least likely to induce or exacerbate heart failure.[130]

ANTHRACYCLINES

The incidence of drug-induced HFrEF is best characterized for the cancer chemotherapy agent doxorubicin. Von Hoff et al.[20] reviewed eight National Cancer Institute trials involving over 3,900 patients and reported an overall incidence of doxorubicin-induced heart failure of 2.2%. However, a retrospective analysis of three clinical trials, which included 630 patients receiving doxorubicin, reported a higher overall incidence of doxorubicin-related HFrEF of 5.1%.[21] In a systematic review of 30 studies, the frequency of anthracycline-induced heart failure in children was reported to be 0–16%.[22] In a cohort of 830 children treated with a mean cumulative anthracycline dose of 288 mg/m^2 during a mean follow-up of 8.5 years, the incidence of anthracycline-induced heart failure was 2.5%.[23] Although anthracyclines can be lifesaving in patients with cancer, the known cardiotoxicity of these agents requires close monitoring with respect to dose and cardiac function.

BIOLOGIC AGENTS

TRASTUZUMAB

Although trastuzumab has clearly been associated with cardiac dysfunction, determination of the incidence is complicated by the coadministration of other cardiotoxic medications such as anthracyclines and cyclophosphamide. In the first large Phase III trial of trastuzumab in patients with metastatic breast cancer that overexpressed human epidermal growth factor receptor 2 (HER2), patients were assigned randomly to standard cancer chemotherapy plus trastuzumab (doxorubicin, epirubicin, or cyclophosphamide for those who had not previously received adjuvant anthracycline therapy or paclitaxel for those who had received previous adjuvant anthracycline therapy) or standard chemotherapy alone. Cardiac dysfunction (based on NYHA criteria) occurred in 27% of the patients receiving an anthracycline, cyclophosphamide, and trastuzumab; in 8% in those who received only an anthracycline and cyclophosphamide; in 13% in those receiving trastuzumab plus paclitaxel; and in 1% of patients receiving paclitaxel alone.[98] In addition, five major trials investigating trastuzumab as adjuvant therapy for patients with HER2 positive breast cancer reported an incidence of severe heart failure (NYHA class III or IV) of 0–3.9% in trastuzumab-treated patients compared with 0–1.3% in control groups.[101,131-135] In these studies, 3–34% of trastuzumab-treated patients experienced >10% reduction in LVEF, compared with 2–17% of patients in control groups (*p* value not reported).[101] In addition, trastuzumab has been used as a single agent in several trials in which the incidence of cardiac dysfunction associated with the drug has been 3–7%.[102] Finally, in a retrospective review of 173 women with metastatic breast cancer who received trastuzumab for at least 1 year at a single institution, 10.9% experienced symptomatic heart failure or had a LVEF between 20% and 40%.[136]

BEVACIZUMAB

Choueiri et al.[137] conducted a meta-analysis of randomized controlled trials of bevacizumab in patients with metastatic breast cancer to evaluate the incidence and the risk of heart failure. They reported that patients who received bevacizumab were at a much higher risk of developing heart failure compared to those who did not receive the drug (RR 4.74, 95% CI 1.84–12.19, $p = 0.001$). No significant difference in the relative risk of heart failure was found between the two approved doses of bevacizumab (2.5 mg/kg and 5 mg/kg, $p = 0.81$).

INFLIXIMAB

Chung et al.[138] conducted a randomized controlled trial to assess the influence of infliximab on clinical outcomes in patients who have moderate-to-severe HFrEF. Patients in this trial were randomized to receive placebo, infliximab 5 mg/kg or infliximab 10 mg/kg (to a maximum of 1 g) immediately after randomization and at 2 and 6 weeks after randomization and were followed for 28 weeks. Patients who received infliximab 10 mg/kg were more likely to have worsened clinical status (NYHA and global assessment) at 14 and 28 weeks compared to patients in the other two groups (placebo and infliximab 5 mg/kg). Those patients were also more likely to die or be hospitalized for HFrEF when compared to the placebo group (HR 2.84, 95% CI 1.01–7.97, $p = 0.043$) and were also more likely to be hospitalized for HFrEF or any other reason when compared to those who received infliximab 5 mg/kg. Of note, reduction in LVEF has been reported in association with lapatinib.[139]

NSAIDs

In a study of more than 10,000 patients over 55 years of age, the adjusted relative risk of hospitalization for heart failure was 1.8 (95% CI 1.4–2.4) in patients receiving diuretics and NSAIDs compared to those taking diuretics only.[79] Bleumink et al.[80] reviewed five studies (including the aforementioned trial) and reported an approximate twofold increase in the relative risk/odds ratio for development of heart failure in patients taking NSAIDs (range between 1.8 [95% CI 1.4–2.4] to 2.2 [95% CI 1–3.4]). Zhao et al.[89] reviewed employers' drug insurance databases to evaluate the cost of heart failure in patients with stable hypertension (and without a history of coronary artery disease or heart failure) who started new treatment with anti-inflammatory medications between January 1999 and September 2000. They reported 102 new outpatient visits for heart failure (based on diagnosis codes and international classification of diseases code) among

20,838 new recipients of prescriptions for traditional NSAIDs (adjusted rate per 1,000 patient-days, 0.124 [95% CI 0.91–1.41, $p = 0.28$]).[89]

COX-2 INHIBITORS

Although the COX-2 inhibitors were originally believed to be free of renal and hemodynamic effects, this has ultimately not proven to be the case. In a randomized, double-blind trial in 1,092 patients ≥65 years of age with hypertension and osteoarthritis, Whelton et al.[87] reported that 0.4% of the patients in the celecoxib group and 0.6% of those in the rofecoxib group developed new onset or worsening of heart failure.[87] In the aforementioned review of patients with stable hypertension in an administrative database, Zhao et al.[89] reported 377 new outpatient visits for heart failure among 19,663 users of celecoxib (adjusted rate per 1,000 patient-days, 0.11) and 228 among 12,218 users of rofecoxib (adjusted rate per 1,000 patient-days, 0.139 [95% CI 1.06–1.48, $p = 0.007$]). In a population-based cohort study in elderly patients, there was an increased risk of hospital admission in patients taking rofecoxib (adjusted rate ratio 1.8, 95% CI 1.4–2.4) and nonselective NSAIDs (adjusted rate ratio 1.4, 95% CI 1–1.9) when compared to those taking celecoxib.[85]

β-BLOCKERS

Although it has been known for some time that β-blockers can precipitate heart failure in susceptible individuals, use of these drugs is now standard care in the management of heart failure, based on morbidity and mortality benefits demonstrated in numerous randomized trials.[1,2,140-142] In 1974, Greenblatt and Koch-Weser[32] reported an incidence of HFrEF of 1% in 319 consecutive hospitalized patients who were prescribed propranolol. These investigators also reviewed 23 studies of 797 outpatients receiving propranolol and reported an incidence of HFrEF of 5.4%. These early results should be balanced against the now incontrovertible evidence supporting the benefit of β-blockers on mortality and morbidity in patients with HFrEF.[1,2,140-142] Indeed, in systematic reviews and clinical trials, the use of β-blockers has been shown consistently to reduce the incidence of mortality in HFrEF by 34% and hospitalizations by 40–50% as compared with placebo.[140,142] In a systematic review of 13 randomized trials of β-blockers, HFrEF was reported as an adverse event in 16.7% of patients receiving β-blockers, compared with 25.1% in those receiving placebo.[140] In an overview of randomized, controlled trials of patients with heart failure comparing β-blockers to placebo, Ko et al.[143] reported that although β-blocker therapy was associated with significant increases in the risk of bradycardia, hypotension, and dizziness, it was also associated with reductions in the incidence of all-cause mortality, hospitalizations for HFrEF, worsening symptoms of HFrEF, and proportion of patients who discontinued therapy with their medications.

MECHANISMS

Mechanisms by which many drugs can induce heart failure can be categorized as those reducing myocardial contractility (calcium-channel blockers, antiarrhythmic agents, anthracyclines, β-blockers), increasing preload (glitazones, NSAIDs, COX-2 inhibitors, corticosteroids), and those increasing afterload (sympathomimetic agents, NSAIDs, and COX-2 inhibitors [via mismatch of vasodilatory and vasoconstrictive prostaglandins]). Mechanisms of drug-induced heart failure are listed in **Table 24-3**. There are several drugs for which the mechanism is unknown, including alogliptin, amantadine, aminocaproic acid, amphotericin B, ampicillin, digoxin immune antibody fragments, bromocriptine, clozapine, cytarabine, dapsone, doxazosin, etanercept, foscarnet, hydralazine, ifosfamide, infliximab, mannitol, pregabalin, saxagliptin, venlafaxine, and zidovudine.

CALCIUM-CHANNEL BLOCKERS

The common mechanism of heart failure associated with the heterogeneous group of calcium-channel blockers is antagonism of L-type calcium channels. All calcium-channel blockers are negative inotropes to varying degrees, but their net effect on cardiac output and symptoms of heart failure depends on other hemodynamic effects in association with the patient's underlying cardiac dysfunction.[144] Verapamil and diltiazem exert strong negative inotropic effects and should be avoided in all patients with HFrEF.[145] Nifedipine demonstrates strong negative inotropic effects in vivo and also causes neurohormonal activation via the renin–angiotensin–aldosterone system.[146] Indeed, nifedipine has been associated with serious exacerbations of HFrEF requiring hospitalization and should be avoided in all patients with left ventricular dysfunction.[39] Second-generation dihydropyridine calcium-channel blockers appear to be more vascular-selective, with a lower potential for worsening heart failure.[118,119] In fact, felodipine and amlodipine have both been evaluated as potential therapeutic agents for heart failure. Neither agent was associated with beneficial effects with respect to patient outcomes. However, neither drug provoked an excess of HFrEF exacerbations compared with placebo, suggesting that these agents may be used safely for other purposes (e.g., hypertension, ischemia) in patients with HFrEF, although other alternatives are available such as long-acting nitrates, β-blockers, and ivabradine.

Table 24-3 Mechanisms of Drug-Induced Heart Failure

Drug	**Mechanism**
Doxorubicin, epirubicin, mitoxantrone	Believed to be related to reduced myocardial contractility Potential mechanisms: Formation of a toxic metabolite Generation of oxygen free radicals Interference with β-adrenergic stimulation of the heart Disturbances in intracellular calcium transport Reduced adenosine diphosphate-stimulated respiration Release of excessive vasoactive compounds such as histamine and catecholamines
Amitriptyline, carbamazepine, clomipramine, diltiazem, disopyramide, encainide, moricizine, flecainide, fluorouracil, imipramine, itraconazole, lidocaine, lorcainide, mexiletine, nifedipine, nortriptyline, propranolol, propafenone, protriptyline, tocainide, verapamil	Reduced myocardial contractility (i.e., negative inotropic effect)
Cabergoline, pergolide	Valvular fibrosis
Aspirin (non-low-dose), celecoxib, diclofenac, diflunisal, etodolac, fenoprofen, flurbiprofen, ibuprofen, indomethacin, ketoprofen, licorice, mefenamic acid, megestrol, meloxicam, minoxidil, nabumetone, naproxen, PEG lavage solution, pioglitazone, piroxicam, prednisolone, rofecoxib, rosiglitazone, sodium-containing antacids, sulindac, tenoxicam, tiaprofenic acid	Increased preload (i.e., fluid retention)
Cyclophosphamide	Endothelial damage, toxic metabolite
Interferon α	Impairment of myocyte metabolism Increased oxygen demand
Blue cohosh, imatinib, anagrelide	Cardiac toxicity
Paclitaxel	Potential exacerbation of anthracycline-induced cardiotoxicity
Sunitinib	Can cause cardiac myocyte apoptosis and mitochondrial injury
Parkinson disease agents	Mechanism unknown, but heart failure may be caused by cardiac valve fibrosis
Etanercept	Blocking the effect of TNFα combined with the other cardiovascular risks of rheumatoid arthritis may cause heart failure

PEG = polyethylene glycol, TNF = tumor necrosis factor.

ANTIHYPERGLYCEMIC AGENTS

GLITAZONES

Although the glitazones appear to have predominantly favorable hemodynamic effects in patients with heart failure, their use has been associated with fluid retention and heart failure.[54-58] Glitazones increase plasma volume by 6–7%.[55] The mechanism of fluid retention is not known, but may be related to increased endothelial-cell permeability or effects on renal hemodynamics.[54] Fluid retention associated with glitazones appears to be refractory to treatment with loop diuretics but is reversible upon discontinuation of therapy.[54,57] However, more recent reports and mechanistic studies suggest that diuretics active in the distal collecting duct (i.e., hydrochlorothiazide and spironolactone) may be effective for reducing the degree of fluid retention associated with glitazones.[147,148]

DPP-4 INHIBITORS

Mechanisms by which DPP-4 inhibitors (saxagliptin and alogliptin) cause an increase in hospitalizations for heart failure is unknown.[149] The results of the currently running large trials (such as the CArdiovascular and Renal Microvascular outcomes study with LINAgliptin in patients with type 2 diabetes mellitus at high vascular risk [CARMELINA] study) will help address questions regarding increasing hospitalization due to heart failure associated with this class of agents.[150]

ANTIARRHYTHMIC AGENTS

Many antiarrhythmic drugs reduce myocardial contractility; the net clinical effects reflect the balance of other hemodynamic effects.[29,151] Disopyramide, flecainide, propafenone, and nondihyropyridine calcium-channel blockers appear to have the strongest negative inotropic effects, whereas amiodarone, ibutilide, and dofetilide appear to have negligible adverse negative inotropic effects.[27,28,151] The ANDROMEDA investigators postulated that dronedarone may directly or indirectly worsen heart failure especially in those with pre-existing poor systolic function, but the mechanism remains unknown.[30]

ANTHRACYCLINES

Although the mechanisms of anthracycline-induced heart failure have not been entirely elucidated, oxidative damage may play a role.[152] Formation of a toxic metabolite, generation of oxygen-free radicals, interference with myocardial β-adrenergic stimulation, disturbances in intracellular calcium transport, reduced adenosine diphosphate–stimulated respiration, or release of excessive vasoactive compounds such as histamine and catecholamines have all been suggested as possible mechanisms.[152,153] Although anthracycline-induced heart failure is generally considered irreversible, case reports of complete recovery after doxorubicin-induced cardiac dysfunction have been published.[9,152,154] The risk of doxorubicin-induced cardiac dysfunction is largely dose-dependent, yet cardiotoxicity can occur with low doses in high-risk individuals.[155]

BIOLOGIC AGENTS

Mechanisms by which biologic agents induce cardiovascular toxicity are not well understood. However, the mechanism of therapeutic effect may play an important role. Mechanisms of heart failure induced by specific biologic agents are described below.

TRASTUZUMAB

The mechanism of trastuzumab-induced HFrEF is unknown but is different from that induced by the anthracyclines.[101] Trastuzumab cardiotoxicity is associated with decreased contractility rather than myocyte death.[156] This is supported by myocardial biopsies obtained from patients with trastuzumab-induced cardiac dysfunction, which do not show typical ultrastructural changes (vacuolization or myocyte dropout) on electron microscopy.[157] Data from in vivo and in vitro studies suggest that the mechanism of trastuzumab-induced heart failure may be partially related to direct HER2 blockade and may be associated with disruption of the epidermal growth factor signaling system that is present within the heart.[101,158] Trastuzumab-induced cardiac dysfunction does not appear to be related to cumulative trastuzumab dose and is largely reversible (although the reduction in LVEF persisted in certain patients after discontinuing therapy with trastuzumab), and rechallenge is generally well tolerated.[101,159]

BEVACIZUMAB

Bevacizumab inhibits vascular endothelial growth factor (VEGF) receptors, which may lead to reduction in LVEF and HFrEF via inhibition of angiogenisis and myocardial tissue growth in the heart.[137]

INFLIXIMAB

Infliximab binds with high affinity to the soluble and transmembrane forms of tumor necrosis factor α (TNFα), inhibiting binding of TNFα to its receptor.[150] Blocking the effect of TNFα, combined with other cardiovascular risk factors (such as diabetes, hypertension, and history of cardiovascular events) in patients with rheumatoid arthritis can cause HFrEF or HFpEF.[112]

NSAIDs AND COX-2 INHIBITORS

NSAIDs are a chemically diverse group of compounds associated with a common mechanism of action, which is inhibition of the COX enzyme. In patients with heart failure, kidney homeostasis is maintained mostly by renal prostaglandin E_2 (PGE_2). Inhibition of COX by NSAIDs disrupts kidney homeostasis and leads to sodium and water retention and exacerbation of symptoms of heart failure.[80,160] These drugs have also been reported to antagonize the actions of angiotensin-converting enzyme (ACE) inhibitors and diuretics.[160] There appears to be little clinically important difference between these agents in terms of their potential to exacerbate symptoms of heart failure.[160,161] The mechanism of sodium and fluid retention associated with COX-2 inhibitors is similar to that of NSAIDs.[89,161]

β-BLOCKERS

β-blockers reduce myocardial contractility through competitive antagonism of β1-receptors. β-blockers may initially exacerbate heart failure, especially if initiated at a high dose or with rapid dose increases. However, during chronic therapy, carvedilol, metoprolol, and bisoprolol have been shown to improve LVEF and to reduce the incidence of HFrEF hospitalization and mortality.[140,142] Several mechanisms have been postulated to explain the beneficial effect of β-blockers in heart failure, including reduction in long-term exposure to catecholamines; restoration of myocardial inotropic and chronotropic responsiveness; reduction in circulating plasma concentrations of vasoconstrictors such as norepinephrine, renin, and endothelin reduction in myocardial gene production of inflammatory cytokines; attenuation of left ventricular remodeling; and reduction in the frequency of ventricular premature beats and incidence of sudden cardiac death.[162]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The clinical presentation of patients with drug-induced heart failure is not different from that from other causes. Symptoms may occur gradually following initiation of a culprit drug. Signs and symptoms associated with drug-induced heart failure are presented in **Table 24-4**.

The differential diagnosis of drug-induced versus other causes of heart failure or exacerbation of heart failure symptoms may be difficult to distinguish from other common precipitants, such as sodium and fluid excess, ischemia, poor adherence to medical therapy, uncontrolled hypertension, arrhythmias (especially atrial fibrillation), systemic infections, impairment in kidney function, anemia, thyrotoxicosis, ethanol ingestion, pulmonary embolism, and respiratory insufficiency (**Table 24-5**).[31,112-117] In general, a temporal sequence of administration of a new potentially offending agent (or dose increase) with increasing symptoms of heart failure heightens the suspicion of a drug-induced cause.

For most drugs that induce heart failure, worsening symptoms of heart failure begin shortly (within days) after initiation of therapy with the drug or increasing the dose. For those drugs causing fluid retention, plasma volume expansion may take several days to manifest in symptoms of dyspnea.

Table 24-4 Signs and Symptoms Associated with Drug-Induced Heart Failure

- Abdominal pain
- Ascites
- Bloating
- Cough
- Diminishing cognitive function (especially in older patients)
- Dyspnea
- Fatigue
- Gallop rhythm
- Hemoptysis
- Hepatojugular reflux
- Hepatomegaly
- Jugular venous distention
- Nausea
- Nocturia
- Orthopnea
- Paroxysmal nocturnal dyspnea
- Peripheral edema
- Pleural effusion
- Pulmonary edema
- Rales
- Third heart sound (S3)
- Weakness

Table 24-5 Conditions to Consider in the Differential Diagnosis of Drug-Induced Heart Failure

- Anemia
- Arrhythmias (especially atrial fibrillation)
- Hypertensive emergency
- Impairment in kidney function
- Myocardial ischemia/infarction
- New onset heart failure (nondrug-induced)
- Pulmonary embolism
- Respiratory insufficiency
- Sodium and fluid excess

- Systemic infections
- Thyrotoxicosis
- Uncontrolled hypertension
- Valve disease

RISK FACTORS

Risk factors for drug-induced heart failure are presented in **Table 24-6**. The most important risk factor for the development of drug-induced heart failure is pre-existing symptomatic or asymptomatic left ventricular dysfunction.[9] In general, older patients are more susceptible to drug-induced diseases; whether this factor applies to drug-induced heart failure is not known.

ANTIHYPERGLYCEMIC AGENTS

GLITAZONES

In their review of 111 consecutive patients with diabetes and systolic heart failure treated with a glitazone, Tang et al.[55] noted upon univariate analyses that females and insulin users were at increased risk of fluid retention. Interestingly, these authors found no association between baseline severity of heart failure and the occurrence of fluid retention. Risk factors for glitazone-induced heart failure, including those described by the American Heart Association/American Diabetes Association consensus statement, are presented in Table 24-6.[56]

DPP-4 INHIBITORS

To be eligible to take part in the published cardiovascular safety trials of DPP-4 inhibitors, patients had to be at high risk for cardiovascular events, including acute coronary syndrome, clinical events associated with atherosclerosis (age 40 years or over) and dyslipidemia, or hypertension or smoking combined with age 55 years or older (males) or 60 years or older (females).[122-124] Pre-existing heart failure was the predominant risk factor for the development of heart failure associated with DPP4-inhibitors.[122-124]

ANTIARRHYTHMIC AGENTS

As with most other heart failure–inducing agents, the predominant risk factor for the development of antiarrhythmic-induced HFrEF is pre-existing left ventricular dysfunction.[29] Unfortunately, patients with HFrEF are also at high risk for sudden cardiac death. Risk versus benefit evaluation is extremely important in this patient population as many antiarrhythmic agents worsen heart failure symptoms. Amiodarone, dofetilide, and ibutilide are the antiarrythmic agents that are associated with minimal effects on myocardial contractility.[130]

Table 24-6 Risk Factors for Drug-Induced Heart Failure

Antiarrhythmic agents

- Pre-existing heart failure

DPP-4 inhibitors

- Pre-existing heart failure

Glitazones

- Pre-existing left ventricular dysfunction
- History of myocardial infarction
- History of symptomatic coronary artery disease
- Hypertension
- Left ventricular hypertrophy
- Significant aortic or mitral valve disease
- Advanced age (>70 years)
- Long-standing diabetes (>10 years)
- Pre-existing edema
- Current treatment with loop diuretics
- Development of edema or weight gain
- Insulin coadministration
- Chronic kidney disease

Anthracyclines

- Cumulative doxorubicin dose (≥550 mg/m^2)
- Three-week schedule of administration
- Older age
- Concomitant cardiac irradiation
- Concomitant use of cyclophosphamide, amsacrine, fluorouracil, dactinomycin, mithramycin, mitomycin, or vincristine
- Children:
  - Higher cumulative dose
  - Cardiac irradiation
  - Age at treatment (<4 years)
  - Maximal dose within 1 week (>45 mg/m^2)
  - Time since treatment (within 1 week of treatment)
  - Use of daunorubicin (as opposed to doxorubicin)
  - Amsacrine
  - Black race
  - Female sex
  - Trisomy 21

Biologic agents

- Older age

- Higher body-mass index
- Antihypertensive therapy
- Lower pretrastuzumab left ventricular ejection fraction
- Concurrent anthracycline use
- Cumulative anthracycline dose
- Concurrent taxanes and capecitabine
- Pre-existing rheumatoid arthritis
- History of coronary heart disease

DPP = dipeptidyl peptidase.

ANTHRACYCLINES

Risk factors for anthracycline-induced HFrEF have been well-described (Table 24-6).[20,22,152,153] Von Hoff et al.[20] reported an increasing risk of heart failure associated with increasing cumulative doses of doxorubicin. The schedule of administration also appears to influence the risk of doxorubicin-induced heart failure; weekly doses were associated with a significantly lower incidence of HFrEF as compared with larger doses on a 3-week schedule (single dose repeated every 3 weeks or three consecutive daily doses repeated every 3 weeks).[20] There is a general increase in the risk of development of doxorubicin-induced heart failure with increasing age. However, the incidence of doxorubicin-induced heart failure is higher in children (younger than 15 years of age) than in adults. All three of these risk factors (total dose, schedule of administration, and age) remained as independent predictors of the development of heart failure after multivariate analysis.[20] The use of other antitumor therapies such as cardiac irradiation and specific antineoplastic agents may also increase the risk.[152] Risk factors for drug-induced heart failure in children receiving anthracycline therapy are also presented in Table 24-6. Kremer et al.[22] determined that the multivariate risk factors were a maximal dose >45 mg/m^2 within 1 week and the use of daunorubicin.

BIOLOGIC AGENTS

Risk factors for heart failure induced by biologic agents include older age, higher body-mass index,antihypertensive therapy, lower pretrastuzumab LVEF, concurrent anthracycline therapy, concomitant therapy with taxanes and capecitabine, cumulative anthracycline dose, rheumatoid arthritis, and history of coronary heart disease.[98,112,131,132,137,163,164]

MORBIDITY AND MORTALITY

Mortality associated with heart failure is very high, with an annual mortality incidence of 5–10% in patients with mild disease and up to 30–40% in those with more advanced disease.[3] The incidence of in-hospital mortality associated with heart failure is 3.5–15%.[4,6] Moreover, about 20–50% of patients discharged alive from the hospital with heart failure are readmitted within the subsequent 6–12 months.[4,165]

Specific data regarding the incidence of morbidity and mortality associated with drug-induced heart failure are scarce. Doxorubicin-induced heart failure is associated with a mortality rate between 30 and 60%.[20,153] Clearly, there is a need for more epidemiologic data to address the prognosis associated with drug-induced heart failure.

PREVENTION

Obviously, the best preventive measure is to avoid the offending agents (**Table 24-7**). Although this is not always possible, particular caution should be exercised in patients with pre-existing left ventricular dysfunction.

Table 24-7 Approaches to Help Prevent Drug-Induced Heart Failure

- Avoid potentially causative agents
- Prevent anthracycline-induced cardiomyopathy with coenzyme Q10, carnitine, pretreatment with antihistamines, cromolyn sodium, probucol, or dexrazoxane (when the cumulative dose of doxorubicin reaches 300 mg/m^2)
- Prevent β-blocker–induced heart failure by starting at low doses with slow careful titration of doses over 6–8 weeks

Because of the high incidence of drug-induced heart failure, diltiazem, verapamil, disopyramide, flecainide, and propafenone should be considered contraindicated in patients with heart failure or asymptomatic left ventricular dysfunction (LVEF <0.40). As mentioned previously, felodipine and amlodipine are safer alternatives in patients with heart failure, as compared with nondihydropyridine calcium-channel blockers or nifedipine. In general, patients with diabetes and heart failure should be treated in a similar manner to those without heart failure, with the exception that diabetes-related comorbidities may influence drug doses and monitoring of therapy. Alternatives to glitazones for blood-glucose control include insulin secretagogues (e.g., sulfonylureas, meglitinides), metformin (in those with an estimated glomerular filtration rate >30 mL/min), α-glucosidase inhibitors, incretin agents, and insulin.[166,167] To date, DPP-4 inhibitors are the most studied class of diabetes medications.[168] Overall, these agents do not increase the risk of cardiovascular death, stroke, or myocardial infarction,but their association with the risk of heart failure remains uncertain.[126,168]

More well-powered studies are required to determine this relationship.[168] The Empagliflozin Cardiovascular Outcome Event Trial in Type 2 Diabetes Mellitus Patients (EMPA-REG Outcomes) study investigators compared the effect of empagliflozin and placebo on cardiovascular morbidity and mortality in adults with type 2 diabetes and established cardiovascular disease.[169] They reported lower rates of death from cardiovascular causes, nonfatal myocardial infarction, or nonfatal stroke in the empagliflozin group when compared to placebo (HR 0.86, 95% CI 0.74–0.99, p <0.001). They also reported less hospitalization for heart failure in the empagliflozin group (HR 0.65, 95% CI 0.50–0.85, $p = 0.002$).[169]

A number of agents have been suggested for reducing the incidence of anthracycline-induced cardiomyopathy including coenzyme Q10, carnitine, pretreatment with antihistamines, antiadrenergics, cromolyn sodium, probucol, dexrazoxane, *N*-acetylcysteine, vitamin E, amifostine, carvedilol, ACE inhibitors, vitamin A, vitamin C, selenium and glutathione.[152,170,171] Dexrazoxane (60–900 mg/m^2 with 60 mg/m^2 of doxorubicin or 500 mg/m^2 with 50 mg/m^2 of doxorubicin) is indicated for reduction of the incidence and severity of cardiomyopathy associated with doxorubicin in women with breast cancer who received a cumulative dose of 300 mg/m^2 and who would benefit from further doxorubicin administration.[152] Dexrazoxane is not indicated for use during the initiation of therapy with doxorubicin. Other potential strategies to limit anthracycline toxicity include limiting the cumulative dose of anthracycline, replacing bolus administration with slow infusion, and using liposomal anthracyclines in place of traditional formulations.

Depending on the indication, several alternatives to NSAIDs or COX-2 inhibitors exist. For example, for the treatment of osteoarthritis in the presence of heart failure, nonpharmacologic (e.g., physical therapy), traditional pharmacologic (e.g., acetaminophen, intraarticular steroid injections), and nontraditional pharmacologic (e.g., glucosamine) therapies may be preferable. It has been reported that if administered in low doses for a short period of time, nonprescription NSAIDs may be associated with much lower risk of adverse events and drug–drug interactions.[172,173] In patients initiated on β-blockers for heart failure, starting therapy at low doses with slow and careful titration over 6–8 weeks or more will help to minimize the likelihood of an exacerbation of HFrEF.[1,2,142]

Excessive alcohol consumption is associated with cardiomyopathy.[174] The mechanism of this change is not well understood but reduced myocardial contractility has been suggested as one of the main causes.[175] Individuals who consume excessive amounts of alcohol were at higher risk for developing heart failure when compared to those who do not drink alcohol.[176] It has been reported that low-to-moderate alcohol consumption is associated with reduced risk of heart failure, but due to the lack of a high-level evidence, more studies are required to understand this relationship.[177]

MANAGEMENT

The management of drug-induced new-onset heart failure and acute exacerbations of heart failure symptoms includes aggressive diuresis and general supportive care.[1,178] Following discontinuation of therapy with the offending agent, management of drug-induced heart failure exacerbations is the same as the usual management of heart failure. Generally, recovery of the myocardium is related to the elimination half-life of the offending agent (the exception is doxorubicin, with an average onset of recovery of 30 days after the last dose).[20] Reduction or abstinence from alcohol consumption was associated with improvement in cardiac function in patients with alcoholic cardiomyopathy.[179] After the acute event, clinicians should be vigilant in ensuring that all patients with heart failure are receiving all efficacious therapies (and at target doses), including ACE inhibitors or angiotensin receptor blockers, neprilysin inhibitors, β-blockers, and, in selected patients, spironolactone or digoxin or both.[1,2] Traditional NSAID and COX-2 inhibitor–induced heart failure is a particularly vexing clinical problem, as many patients with heart failure have osteoarthritis and gout, which negatively impact quality of life, and these patients could otherwise benefit from these therapies. In these situations, alternative nonpharmacologic and pharmacologic therapies (e.g., acetaminophen) may be preferable. Rechallenge with drugs that have induced or exacerbated heart failure is generally not recommended.

The high prevalence of heart failure and the clinical fragility of such patients suggest that pharmacists’ close monitoring can have a great impact. In a systematic review of 12 randomized trials that included 2,060 patients, the addition of a pharmacist to the heart failure team resulted in a 31% reduction in heart failure hospitalizations.[180] Pharmacists can identify patients at risk for drug-induced heart failure, identify drug-induced causes of exacerbations of symptoms of heart failure, guide treatment choices to avoid agents that could exacerbate heart failure, institute appropriate preventive measures when necessary, counsel patients with heart failure on the use of nonprescription medications, and ensure that patients are receiving all proven efficacious therapies for heart failure (ACE inhibitors, neprilysin inhibitors, β-blockers, spironolactone, digoxin) at target doses.

INFORMATION FOR PATIENTS

When the use of a potentially offending agent is unavoidable in patients with HFrEF, patients should be alerted to the signs and symptoms of heart failure. Early detection and treatment of drug-induced heart failure may prevent hospitalization or death. Healthcare personnel should be alerted if the patient develops any of the following: shortness of breath, loss of appetite, rapid weight gain, swelling in lower limbs, abdominal swelling and/or pain, frequent dry hacking cough, increased fatigue with less effort, or difficulty falling asleep.[181,182] This is particularly important in light of studies that have shown that even in patients with long-standing heart failure, knowledge of signs and symptoms is very poor.[183,184] All patients with heart failure should be alerted to the dangers of nonprescription therapies such as NSAIDs, licorice-containing herbal remedies, and sympathomimetics such as those in cough and cold preparations. Patients with heart failure should consult their physician or pharmacist prior to initiating therapy with any new medications, including nonprescription and herbal remedies. Education of patients and their families and friends is very important to improve patients' recognition of early warning symptoms and signs, ensure early intervention before acute heart failure deterioration, and avoidance of exacerbations of drug-induced heart failure. In addition, patients should weigh themselves daily to track changes in body weight that might be indicative of fluid retention (>1 kg/day). In certain situations, patients may be taught how to adjust their diuretic dose based on these changes in body weight and symptoms.

CHAPTER 25

Ventricular Arrhythmias

James E. Tisdale

Drugs may induce potentially life-threatening ventricular arrhythmias. Drug-induced ventricular arrhythmias can be divided into three categories: monomorphic ventricular tachycardia, the polymorphic ventricular tachycardia known as torsades de pointes (TdP), and drug-induced Brugada syndrome.

MONOMORPHIC VENTRICULAR TACHYCARDIA

CAUSATIVE AGENTS

Drugs that have been reported to cause or exacerbate monomorphic ventricular tachycardia are listed in **Table 25-1**.[1-177] Any of the drugs listed may cause new monomorphic ventricular tachycardia. Incessant, sinusoidal-appearing ventricular tachycardia is most often associated with the potent sodium-channel blocking agents belonging to the Vaughan Williams antiarrhythmic class IC (e.g., flecainide, propafenone), although it has also been reported in association with amiodarone. Nonsustained and sustained ventricular tachycardia have been widely reported in association with dobutamine during stress echocardiography. Although ventricular arrhythmias are a known risk associated with stress echocardiography, the incidence of ventricular tachycardia associated with dobutamine stress echocardiography is significantly higher than that associated with exercise stress echocardiography.[77,79]

EPIDEMIOLOGY

Although the overall incidence of drug-induced ventricular tachycardia is not known, the incidences associated with some specific drugs have been reported (Table 25-1). Ventricular tachycardia is recognized as a consequence of digoxin toxicity.[34-38] The incidence of ventricular tachycardia in patients taking digoxin is unknown. However, in an analysis of patients discharged from a major urban medical center with the diagnosis of digoxin intoxication, 7% had "definite" ventricular tachycardia.[35]

Table 25-1 Agents Implicated in Drug-Induced Monomorphic Ventricular Tachycardia

Drug	Incidence	Level of Evidence[a]
Aconite alkaloids[1-8]	NK	C
Acetylsalicylic acid[9,b]	NK	C
Adenosine[10-16]	Up to 5%	B
Amiodarone[17,18]	NK	C
Arsenic trioxide[19]	NK	C
Bupropion[20]	NK	C
Bupivacaine[21-25]	NK	C
Chlorpromazine[26]	NK	C
Citalopram[27,b]	NK	C
Cocaine[28-30]	NK	B
Desipramine[31-33,b]	NK	C
Digoxin[34-38]	NK	A
Dipyridamole[39-41]	0.03–0.8%	B
Disopyramide[42]	NK	C
Dobutamine[41,43-85]	0–15.7%[c]	A
Ephedrine[86,87]	NK	C

Flecainide[88-122]	0–13%	A
Gingko biloba[123]	NK	C
Ibutilide[124-131]	0–9.8%	A
Imipramine[132]	NK	C
Lacosamide[133]	NK	C
Lamotrigine[134]	NK	C
Levosimendan[135,136]	NK	A
Lithium[137,d]	NK	C
Methamphetamine[138]	NK	C
Milrinone[44,139-142]	0–9.5%	B
Niferidil[143]	3.7%	B
Procainamide[144]	NK	C
Propafenone[145-158]	0–10%	B
Ropivacaine[159,160]	NK	C
Sotalol[161]	NK	C
Terbutaline[162-164]	0–15%[e]	A
Theophylline[164-174]	NK	B
Thioridazine[32]	NK	C
Trazodone[175,176]	NK	C
Venlafaxine[134,177,b]	NK	C

NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Primarily in overdose.

[c] Reported as high as 29% in patients with severe heart failure.

[d] Chronic toxicity.

[e] 15% incidence reported in patients with a history of ventricular arrhythmias.

MECHANISMS

Mechanisms of drug-induced monomorphic ventricular tachycardia vary depending on the causative agent(s) (**Table 25-2**). Many of the drugs that cause monomorphic ventricular tachycardia (e.g., amiodarone, chlorpromazine, disopyramide, flecainide, imipramine, procainamide, propafenone) do so as a result of potent inhibition of myocardial sodium channels, leading to a reduction in ventricular conduction velocity.[158] This changes the relationship between ventricular conduction velocity and ventricular refractoriness, which may promote the manifestation of re-entrant circuits in ventricular tissue. These drugs may particularly perturb the relationship between ventricular conduction velocity and refractoriness in patients with a history of myocardial infarction in whom alteration of electrophysiologic characteristics has already occurred in the border zone of the infarcted tissue. This is also an important proarrhythmic effect in patients with heart failure with reduced ejection fraction (HFrEF), in whom ventricular electrophysiology is altered as a result of left ventricular hypertrophy and accumulation of connective tissue in the left ventricle. In particular, potent sodium-channel inhibition caused by Vaughan Williams class IC antiarrhythmic agents (e.g., flecainide, propafenone) can lead to incessant, sinusoidal ventricular tachycardia.[178,179]

Table 25-2 Mechanisms of Drug-Induced Monomorphic Ventricular Tachycardia

Drug	Mechanism
Aconite alkaloids	Activate myocardial sodium channels, increasing permeability to sodium and increasing ventricular automaticity
Adenosine	Enhanced activity of the sympathetic nervous system, via increased arterial chemoreceptor and baroreceptor activity Myocardial ischemia due to coronary steal
Amiodarone Bupivacaine Chlorpromazine Desipramine Disopyramide Flecainide Imipramine Procainamide Propafenone Ropivacaine	Inhibition of sodium-channel conductance
Digoxin	Inhibition of the sodium–potassium–adenosine triphosphatase pump, leading to increased intracellular calcium concentrations, resulting in afterdepolarizations and ventricular ectopic activity
Dobutamine Terbutaline	Stimulation of β_2-receptors, leading to ventricular ectopic activity
Theophylline	Phosphodiesterase inhibition, leading to elevated concentrations of cyclic adenosine monophosphate, causing increased intracellular calcium concentrations, resulting in afterdepolarizations and ventricular ectopic activity

Ibutilide Sotalol Trazodone Venlafaxine	Unknown

In contrast to sodium inhibition, aconite alkaloids provoke ventricular tachycardia via activation of myocardial sodium channels and increasing permeability to sodium conductance, delaying ventricular repolarization and increasing ventricular automaticity.[180,181] Adenosine may cause monomorphic ventricular tachycardia as a result of enhancement of arterial chemoreceptor and baroreceptor activity, leading to increased activity of the sympathetic nervous system or due to inducing myocardial ischemia as a result of "coronary steal," or both.[10,182] Digoxin-induced ventricular tachycardia, which is usually a manifestation of serum concentrations that are markedly elevated above the therapeutic range, occurs as a result of profound inhibition of the sodium–potassium–adenosine triphosphatase pump, leading to marked increases in intramyocyte calcium concentrations, provoking afterdepolarizations and ventricular ectopic activity.[183] Like that associated with adenosine, ventricular tachycardia induced by dipyridamole occurs as a result of induced myocardial ischemia due to the phenomenon of "coronary steal."

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Whether drug-induced or due to other causes, monomorphic ventricular tachycardia is defined as a series of consecutive ventricular premature depolarizations and is characterized by wide, misshapen QRS complexes on an electrocardiogram (ECG), with a heart rate >100 bpm, and sometimes as high as 150–250 bpm (**Figure 25-1**). As indicated by the term *monomorphic*, QRS complexes possess similar beat-to-beat morphologic characteristics. Potent sodium channel-blocking drugs may also cause an often incessant ventricular tachycardia characterized by wide QRS complexes with a sinusoidal appearance. This incessant, sinusoidal ventricular tachycardia is often slower than typical spontaneous ventricular tachycardia but occasionally can be quite rapid.[92]

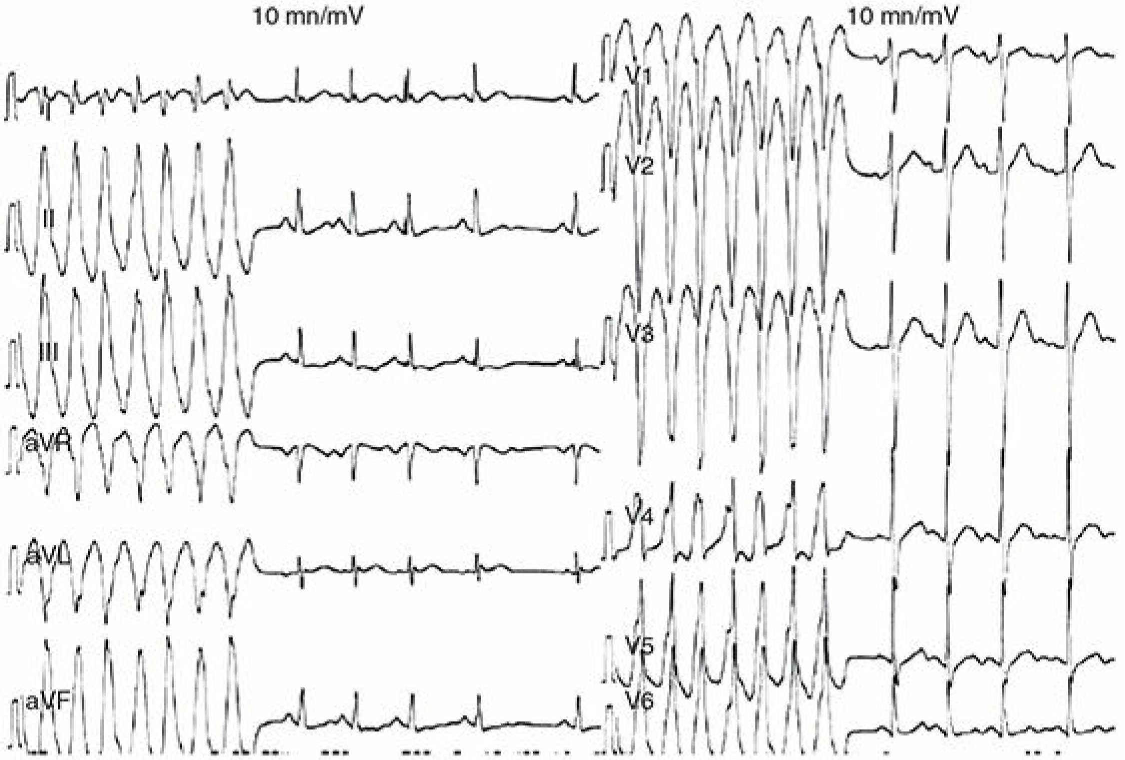

FIGURE 25-1 Monomorphic Ventricular Tachycardia Associated with Weight Loss Pills Containing Caffeine and Ephedrine

Source: Reproduced from Pareek M, Hansson NH, Grove EL. Ventricular tachycardia induced by weight loss pills. *Case Rep Med.* 2013; 2013:712383.

Drug-induced monomorphic ventricular tachycardia may be nonsustained or sustained. Nonsustained ventricular tachycardia is defined as at least three consecutive beats of ventricular tachycardia, lasting ≤30 seconds and terminating spontaneously. Sustained ventricular tachycardia lasts >30 seconds and requires intervention for termination. Sinusoidal-appearing ventricular tachycardia is often sustained and is more likely to be incessant and refractory to overdrive pacing or direct current cardioversion than other monomorphic ventricular tachycardias. Occasionally, sinusoidal-appearing ventricular tachycardia is characterized by frequent nonsustained episodes that terminate spontaneously but quickly recur.[92]

Drugs may cause new ventricular tachycardia in patients who did not previously have this arrhythmia or may aggravate or worsen an underlying ventricular tachycardia. For example, specific drugs may increase the rate of a patient’s pre-existing ventricular tachycardia, make it more symptomatic, more difficult to terminate, or both.[179] The symptoms of drug-induced ventricular tachycardia are related to heart rate and the resultant effect on blood pressure and cardiac output (**Table 25-3**). However, in some patients, the initial symptom of drug-induced ventricular tachycardia may be sudden cardiac death as a result of rapid degeneration of ventricular tachycardia to ventricular fibrillation.

Table 25-3 Signs and Symptoms Associated with Drug-Induced Monomorphic Ventricular Tachycardia

- Chest pain (in patients with underlying coronary artery disease)
- Dizziness
- Hypotension
- Lightheadedness
- Monomorphic ventricular tachycardia on electrocardiogram
- Near-syncope
- Palpitations
- Seizures (due to cerebral hypoxia)
- Shortness of breath
- Sinusoidal ventricular tachycardia on electrocardiogram
- Sudden cardiac death (if ventricular tachycardia is pulseless)
- Syncope
- Tachycardia

The time from drug therapy initiation to the development of drug-induced monomorphic ventricular tachycardia is somewhat variable. In cases of drug overdose or elevated plasma drug concentrations during therapy, the arrhythmia may develop within a few minutes to several hours after the ingestion or the plasma concentration elevation. The majority of cases of drug-induced monomorphic ventricular tachycardia occur within hours to days after the initiation of therapy.

Table 25-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Monomorphic Ventricular Tachycardia

- Atrial fibrillation
- Atrial flutter
- Atrial tachycardia
- Atrioventricular nodal re-entrant tachycardia
- Idioventricular tachycardia
- Junctional tachycardia
- Non-TdP polymorphic ventricular tachycardia
- Sinus tachycardia
- TdP

TdP = torsades de pointes.

Table 25-5 Differentiation of Drug-Induced Monomorphic Ventricular Tachycardia from Nondrug-Induced Ventricular Tachycardia

In patient with no history of VT

- New VT on drug therapy (VT not present before drug therapy)
- No obvious underlying cause for new VT, such as:

  - Ischemic heart disease
  - Heart failure
  - Hypokalemia
  - Hypomagnesemia

In patient with history of VT

- VT on drug therapy:
  - Has a different morphology than patient's previous clinical VT
  - Is substantially faster than patient's previous clinical VT
  - Is sustained, whereas patient previously had only nonsustained VT
  - Is sinusoidal
  - Is more difficult to terminate than patient's previous clinical VT

VT = ventricular tachycardia.

Drug-induced monomorphic ventricular tachycardia must be differentiated from other tachycardias (**Table 25-4**). Further, drug-induced monomorphic ventricular tachycardia must be distinguished from spontaneously occurring nondrug-induced ventricular tachycardia (**Table 25-5**). Diagnosis of drug-induced ventricular tachycardia is usually based on the occurrence of a new ventricular tachycardia in a patient with no history of ventricular tachycardia before the initiation of drug therapy. In addition, drug-induced ventricular tachycardia may be diagnosed in a patient with a history of nondrug-induced ventricular tachycardia if the morphology of the ventricular tachycardia that develops after the initiation of drug therapy differs from that of the ventricular tachycardia that occurred in the absence of drug therapy. The occurrence of incessant sinusoidal ventricular tachycardia may be considered a drug-induced arrhythmia, as this form of ventricular tachycardia has not been described in the absence of drug therapy and is not typical of ventricular tachycardia occurring as a result of myocardial infarction, acute coronary ischemia, left ventricular dysfunction, or other common causes of ventricular tachycardia. Drug-induced ventricular tachycardia may also be diagnosed if a patient's underlying ventricular tachycardia becomes more rapid, more symptomatic, more difficult to terminate after the initiation of therapy with a new drug, or some combination of these factors.

RISK FACTORS

Structural heart disease, particularly a history of myocardial infarction or coronary artery disease even without a history of myocardial infarction, is a major risk factor for ventricular tachycardia induced by potent sodium channel-blocking agents such as flecainide or propafenone (**Table 25-6**).[184] The Cardiac Arrhythmia Suppression Trial[185] was designed to test the hypothesis that suppression of asymptomatic ventricular ectopic activity after a myocardial infarction reduces the incidence of postinfarction mortality. In CAST, patients who had experienced a myocardial infarction within the previous 1 week to 6 months were recruited to enter a run-in study phase in which the efficacy of flecainide, encainide, and moricizine (encainide and moricizine are no longer available in the United States) were tested to determine the efficacy of each agent for the suppression of ventricular ectopic activity. Patients in whom one of these drugs was effective for the suppression of ventricular ectopic activity were then randomly assigned to the most effective (in that specific patient) of the three agents or placebo.

Table 25-6 Risk Factors for Drug-Induced Monomorphic Ventricular Tachycardia

- Coronary artery disease
- HFrEF
- History of arrhythmias (risk factor for dobutamine-induced ventricular tachycardia)
- History of ventricular arrhythmias may be a risk factor for terbutaline-induced ventricular tachycardia
- Hypokalemia, hypomagnesemia, and hypercalcemia are risk factors for ventricular tachycardia associated with digoxin
- Male sex (risk factor for dobutamine-induced ventricular tachycardia)
- Recent myocardial infarction
- Serum digoxin concentrations >2 ng/mL
- Serum theophylline concentrations >20 mcg/mL

HFrEF = heart failure with reduced ejection fraction.

The flecainide and encainide arms of the study were discontinued prematurely as a result of excess mortality in the treatment group. The arrhythmic mortality incidence in the patients who received flecainide or encainide was more than three times higher than in the placebo group.[185] The moricizine arm of the study was continued but, like the flecainide and encainide arms of the original CAST trial, was subsequently discontinued because of an increased incidence of mortality in moricizine-treated patients during the first 2 weeks of treatment.[186] Active treatment with encainide or flecainide was associated with greater mortality than placebo in the majority of subgroups, but patients with non-Q-wave myocardial infarction and frequent premature ventricular complexes were at highest risk.[184] As a result of the findings of CAST, flecainide is contraindicated in patients with a documented history of coronary artery disease. In addition, although propafenone was not included in CAST, as a Vaughan Williams class IC antiarrhythmic drug with potent sodium channel-blocking properties, it is also considered to be contraindicated in patients with a documented history of coronary artery disease, even though there are no studies specifically associating propafenone therapy with increasing mortality incidence. A subsequent meta-analysis of 138 randomized, controlled trials of antiarrhythmic agents that enrolled a total of approximately 98,000 patients with a history of myocardial infarction receiving the drugs for arrhythmia prophylaxis also reported an increased risk of mortality associated with the sodium channel-blocking antiarrhythmic agents from Vaughan Williams class IA (quinidine, procainamide, disopyramide). Although the cause of death in these studies was not documented, proarrhythmia was believed to be the major cause.[187]

HFrEF is also likely a risk factor for drug-induced monomorphic ventricular tachycardia.[188] Some risk factors are drug-specific. For example, serum digoxin concentrations >2 ng/mL—particularly in patients with hypokalemia, hypomagnesemia, or hypercalcemia—is a risk factor for monomorphic ventricular tachycardia caused by digoxin. Serum theophylline concentrations >20 mcg/mL increase the risk of theophylline-induced monomorphic ventricular tachycardia.[170] Patients with a history of ventricular arrhythmias may be at higher risk for monomorphic ventricular tachycardia induced by terbutaline.[163] A history of complex ventricular ectopic activity, HFrEF, and multivessel coronary artery disease are risk factors for dobutamine-induced ventricular tachycardia in patients with a recent myocardial infarction.[46]

MORBIDITY AND MORTALITY

There is little published information regarding the impact of drug-induced monomorphic ventricular tachycardia on hospitalization or emergency department visits, but based on the symptoms associated with this disease, it seems likely that these could be consequences. Drug-induced monomorphic ventricular tachycardia may degenerate into ventricular fibrillation and cause sudden cardiac death. Potent sodium channel-blocking drugs in Vaughan Williams antiarrhythmic classes IA and IC have been shown to increase death due to arrhythmias in patients with a history of myocardial infarction.[185-187]

Nonsustained ventricular tachycardia associated with dobutamine during stress echocardiography may have prognostic significance in patients with HFrEF. Patients without inducible ischemia who had moderately reduced left ventricular ejection fraction (LVEF) (35–45%) who experienced nonsustained ventricular tachycardia during dobutamine stress echocardiography had a significantly lower incidence of survival compared to patients with LVEF >45% during a 3-year follow-up period.[76]

Death has been reported as a result of drug-induced incessant, sinusoidal ventricular tachycardia.[189] The incidence of mortality among patients who experience drug-induced ventricular tachycardia is unknown.

Table 25-7 Prevention of Drug-Induced Monomorphic Ventricular Tachycardia

- Appropriately adjust doses of digoxin, procainamide, and sotalol in patients with kidney disease
- Avoid use of oral Vaughan Williams class IA (quinidine, disopyramide) or class IC (flecainide, propafenone) agents in patients with coronary artery disease

- Avoid use of disopyramide, flecainide, and propafenone in patients with HFrEF
- Avoid concomitant use of hepatically metabolized drugs that may cause monomorphic ventricular tachycardia and drugs that inhibit the cytochrome P-450 enzyme system
- Maintain serum digoxin concentrations <2 ng/mL
- Maintain serum theophylline concentrations <20 mcg/mL
- Maintain serum potassium concentrations within normal range
- Maintain serum magnesium concentrations within normal range

HFrEF = heart failure with reduced ejection fraction.

PREVENTION

The risk of drug-induced ventricular tachycardia may be minimized by avoiding the use of specific causative drugs in high-risk populations and by maintaining serum potassium and magnesium concentrations at >4 and >2 mEq/L, respectively (**Table 25-7**). Flecainide and propafenone are contraindicated in patients with documented coronary artery disease. In addition, long-term use of oral quinidine and disopyramide should be avoided in patients with coronary artery disease. Drugs with substantial potential to impair myocardial contractility, including flecainide, disopyramide, procainamide, propafenone, and sotalol should be avoided in patients with HFrEF. In patients receiving digoxin, serum digoxin concentrations should be maintained at <2 ng/mL, and appropriate dose adjustment is necessary in patients with impaired digoxin clearance due to kidney disease. Similarly, patients receiving procainamide and, in particular, sotalol should undergo appropriate dose adjustment for kidney disease. Serum theophylline concentrations should be maintained at <20 mcg/mL. In patients undergoing dobutamine stress echocardiography, earlier administration of atropine (initiation prior to or at time of initiation of dobutamine) may be associated with a reduced risk of ventricular tachycardia compared with conventional timing of atropine administration (initiated near the end of the dobutamine infusion protocol).[83,84]

MANAGEMENT

In patients with drug-induced monomorphic ventricular tachycardia, the causative agent should be discontinued (**Figure 25-2**). Hemodynamically unstable drug-induced ventricular tachycardia should be terminated using synchronized direct current cardioversion, starting at 100 J monophasic or biphasic shock, and increasing to 200, 300, and 360 J if necessary.[190,191] Ventricular tachycardia is usually considered hemodynamically unstable if it results in acute impairment of vital organ function or cardiac arrest is ongoing or imminent.[181,182] Hemodynamically stable drug-induced monomorphic ventricular tachycardia may be also be treated with synchronized direct current cardioversion, at the energy levels described above, with appropriate sedation prior to shock administration.[192]

Alternatively, hemodynamically stable drug-induced monomorphic ventricular tachycardia may be treated initially with intravenous procainamide, unless procainamide is believed to be the causative agent.[192] Intravenous amiodarone or intravenous sotalol may be administered if hemodynamically stable monomorphic ventricular tachycardia is refractory to procainamide.[192]

FIGURE 25-2 Management of Drug-Induced Monomorphic Ventricular Tachycardia

DCC = direct current cardioversion, IV = intravenous.

[a] 100 Joules (monophasic or biphasic).

[b] 10–17 mg/kg continuous intravenous infusion at a rate of 20–50 mg/min.[192]

[c] 150 mg intravenously over 10 minutes, followed by continuous intravenous infusion of 1 mg/min for 6 hours, followed by continuous intravenous infusion of 0.5 mg/min for 18 hours.[192]

[d] 75 mg every 12 hours.[192]

Incessant sinusoidal ventricular tachycardia is sometimes resistant to direct current cardioversion or overdrive pacing and is often resistant to antiarrhythmic drugs such as procainamide.[108] However, flecainide-induced incessant sinusoidal ventricular tachycardia has been successfully treated with intravenous lidocaine.[107] Flecainide-induced sinusoidal ventricular tachycardia has also been successfully treated using high-dose intravenous amiodarone.[108] Intravenous lipid emulsion has been used successfully for management of ventricular tachycardia associated with bupivacaine and local anesthetics.[22,23,193,194]

INFORMATION FOR PATIENTS

Patients who are taking drugs that may cause ventricular tachycardia should be told that the medication may, in rare cases, cause the heart rate (pulse) to become faster. Patients should be instructed to consult their pharmacist or physician if their heart rate increases to above 100–120 bpm or if they feel palpitations, lightheaded, dizzy, tired, weak, short of breath or experience chest pain.

TORSADES DE POINTES

TdP is a potentially life-threatening ventricular tachyarrhythmia associated with prolongation of the heart rate-corrected QT (QTc) interval.[195,196] QTc interval prolongation and TdP may be congenital or acquired. Acquired TdP is most often caused by drugs.[197]

CAUSATIVE AGENTS

Drugs that have been reported to cause TdP are presented in **Table 25-8**.[26,197-670] Up-to-date lists of drugs associated with TdP may be found at https://crediblemeds.org/index.php/login/dlcheck, a website maintained by the Arizona Center for Education and Research on Therapeutics.[197] This site categorizes QTc interval-prolonging drugs according to whether they are associated with a known risk, possible risk, or conditional risk of TdP. Known risk includes those drugs for which “substantial evidence supports the conclusion that these drugs prolong the QT interval AND are clearly associated with a risk of TdP, even when taken as directed in official labeling.”[197] Possible risk includes those drugs for which “substantial evidence supports the conclusion that these drugs can cause QT prolongation BUT there is insufficient evidence at this time that these drugs, when used as directed in official labeling, are associated with a risk of causing TdP.”[197] Conditional risk includes those drugs for which “substantial evidence supports the conclusion that these drugs are associated with a risk of TdP BUT only under certain conditions (e.g., excessive dose, hypokalemia, congenital long QT or by causing a drug–drug interaction that results in excessive QT interval prolongation).”[197] Drugs associated with a risk of TdP are categorized in Table 25-8 based on these definitions.

Table 25-8 Agents Implicated in Drug-Induced Torsades de Pointes

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Incidence was 0.97% of patients taking azithromycin who had QTc interval >450 msec, not 0.97% of all patients taking the drug.

[c] Incidence varies depending on the presence or absence of heart failure with reduced ejection fraction and whether or not dose is adjusted appropriately in patients with kidney disease. The incidence is as high as 10% when proper dose adjustment is not performed.

[d] Intravenous haloperidol in critically ill patients.

[e] Incidence depends on whether or not drug dose is adjusted appropriately in patients with kidney disease.

[f] In overdose.

EPIDEMIOLOGY

The incidence of drug-induced TdP in the general population is unknown. An attempt was made to determine the overall incidence of drug-induced ventricular proarrhythmia in a study conducted by the Swedish Medical Products Agency.[671] This study was conducted over a period of 28 days in 32 hospitals, with a reference population of approximately 4.2 million people. All episodes of ventricular arrhythmias that were encountered during admission to the hospital or that were tracked by ambulatory ECG recordings in the hospitals and that were considered to be associated with drugs were recorded. Fourteen cases of medium or high confidence TdP were recorded. This corresponded to an incidence of 3.3 cases per million during the 28-day period of the study, which was annualized to an incidence of 4 cases per 100,000 people annually.[627] This study was very small and of very short duration. Nonetheless, if this incidence could be extrapolated to the U.S. population, it would correspond to nearly 13,000 cases of drug-induced TdP annually. However, a more recent study conducted in Berlin estimated the annual incidence of drug-induced long QT syndrome (LQTS)/TdP in that city to be 2.5 per million in men and 4 per million in women.[672] Extrapolation of those estimates to the U.S. population suggests a lower incidence of drug-induced LQTS/TdP, about 400 cases annually in men and 660 cases per women, for an annual number of about 1,060 cases.

In another study conducted in Sweden, reports to the Swedish adverse drug reaction reporting system between 1991 and 2006 were analyzed.[673] Of 61,788 reported adverse drug reactions, 101 were drug-induced TdP. In a population-based study conducted in southwest France, drug-induced TdP was estimated to comprise 5–7% of all cases of ventricular tachycardia, ventricular fibrillation, or sudden cardiac death.[674] These studies did not attempt to determine the overall incidence of drug-induced TdP in the population. The actual incidence of drug-induced TdP in the United States remains unknown and requires further study. The incidence of TdP associated with specific agents is presented in Table 25-8.

QTc interval prolongation is common among hospitalized patients, particularly those in intensive care units (ICUs). In a study conducted in 900 consecutive patients admitted to two cardiac ICUs at a large academic medical center, QTc interval prolongation was present in 28% of patients on admission, and 18% had a QTc interval >500 msec.[675] Of these, 35% and 42%, respectively, were subsequently prescribed QT interval–prolonging drugs, despite being admitted with QTc interval prolongation.[675] In another investigation, 24% of patients in adult ICU and progressive care units developed QTc interval prolongation.[676] In a prospective cohort study of patients admitted to a mixed medical-surgical ICU, 52% had a QTc interval >500 msec during the ICU stay.[677] The prevalence of QTc interval prolongation among patients in an emergency department was 35% (95% CI 32–37%), with 8% of patients having a QTc interval>500 msec.[678]

The incidence of TdP in hospitalized patients has not been widely studied. Pickham et al. reported one case of TdP among 154 patients (0.6%) in adult ICUs and progressive care units during a 2-month period, representing 1 of 16 cardiac arrests (6%) in these units.[676]

MECHANISMS

TdP occurs in the setting of prolongation of ventricular repolarization resulting in lengthening of ventricular action potential duration, which is manifested as prolongation of the QTc interval on the ECG.[195,196,679] As a result of activation of inward depolarizing currents, action potential prolongation leads to increased susceptibility to early afterdepolarizations, which are manifested as depolarizing oscillations in membrane voltage during phase 2 or 3 of the action potential.[195] These early afterdepolarizations may result in triggered upstrokes, which, when occurring during the latter portion of phase 3 of the action potential, may initiate TdP via re-entry.[679]

Prolongation of ventricular repolarization and resulting action-potential duration lengthening may occur as a result of decreases in outward current or increases of inward current during the plateau or repolarization phase of the action potential (or both). Drugs induce TdP through inhibition of outward current through specific potassium channels, primarily the rapid component of the delayed rectifier potassium current (I_{Kr}), resulting in action potential prolongation.[195,196,679] Some drugs, such as ibutilide, also appear to prolong ventricular action potential in part through activation of slow sodium current during phase 2 of the action potential. It is believed that early afterdepolarizations that trigger TdP may be caused by increased inward calcium current through calcium channels that become reactivated as a result of prolongation in action potential duration.[195,679,680]

Although inhibition of I_{Kr} current and/or activation of late sodium current and prolongation of ventricular repolarization and the corresponding QTc interval are requisite for the development of TdP, those factors alone are not sufficient for the arrhythmia to occur. Many patients taking drugs that inhibit I_{Kr} current develop QTc interval prolongation but do not experience TdP. A major factor that is believed to increase the likelihood of TdP, and which may in part explain the lack of a direct correlation between QTc interval and the occurrence of TdP, is heterogeneity of repolarization (also referred to as dispersion of repolarization or refractoriness).[195] Action potential duration varies throughout the three primary ventricular cell types (epicardial, mid-myocardial [M cells], endocardial) as a result of variations in ion currents in the different cell types. The risk of drug-induced TdP is believed to be enhanced in patients with increased transmural dispersion of ventricular refractoriness. In addition, evidence exists to suggest that the risk of TdP may be dependent on instability of the action potential and by the degree of triangulation of the action potential. Instability of the action potential indicates rapid fluctuations in action potential duration. Triangulation of the action potential refers to the repolarization time from action potential duration at 30% repolarization to action potential duration at 90% repolarization; as this time increases, the action potential takes on a more triangular shape. In vitro and ex vivo studies have suggested that the risk of TdP is enhanced when action potential instability and triangulation are present.[681] Further study is required to better understand the conditions required for TdP to develop in patients with QTc interval prolongation.

An important concept with respect to drug-induced TdP is that of repolarization reserve.[682] Under normal conditions, there are multiple redundant mechanisms that maintain normal ventricular repolarization, which include I_{Kr} but also other repolarizing currents, including the slow component of the delayed rectifier potassium current (I_{Ks}), inward sodium current (I_{Na}), L-type inward calcium current ($I_{Ca,L}$), inward rectifier potassium current (I_{k1}), transient outward potassium current (I_{to}), sodium-potassium pump current ($I_{Na/K}$), and sodium/calcium exchange current (I_{NCX}).[683] Inhibition of I_{Kr} with a drug in the presence of fully intact repolarization reserve rarely results in TdP, as the redundancy in repolarizing currents minimizes the impact of I_{Kr} inhibition. However, in the presence of circumstances that diminish repolarization reserve, such as risk factors for TdP (discussed below), drug-induced I_{Kr} inhibition may have a much greater impact on prolonging ventricular repolarization and result in TdP.[682,683]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Symptoms associated with TdP are similar to those of other tachyarrhythmias and are related to heart rate and resulting effects on blood pressure and cardiac output (**Table 25-9**). Although TdP is sometimes transient, self-limiting, and spontaneously terminating, it can degenerate into ventricular fibrillation and cause sudden cardiac death.

Table 25-9 Signs and Symptoms Associated with Drug-Induced Torsades de Pointes

- Chest pain (in patients with underlying coronary artery disease)
- Dizziness
- Hypotension
- Lightheadedness
- Near syncope
- Often a "short-long–short" initiating sequence on electrocardiogram
- Palpitations
- Seizure (due to cerebral hypoxia)
- Shortness of breath
- Syncope
- Syndrome of sudden cardiac death
- Tachycardia
- Torsades de pointes on electrocardiogram—polymorphic ventricular tachycardia in setting of prolonged QTc interval

QTc = corrected QT.

The diagnosis of TdP is dependent on the ECG. TdP is a specific polymorphic ventricular tachycardia associated with prolongation of the QTc interval in the sinus beats that precede the arrhythmia. QT interval correction is necessary because the QT interval varies depending on the heart rate; as heart rate increases, the QT interval shortens, and vice versa. There are numerous published formulas for correcting the QT interval, but that which is most commonly used in practice, and which is programmed into ECG machines, is the Bazett's correction: QTc = QT interval/√RR interval.[684]

TdP, or "twisting of the points," is characterized by the apparent twisting of the wide QRS complexes around the isoelectric baseline (**Figure 25-3**) and occurs at rates of 160–240 bpm.[685,686] A characteristic feature of TdP is a short-long-short initiating sequence (Figure 25-3), which occurs as a result of a ventricular premature beat followed by a compensatory pause that is followed by the first beat of the TdP.[687]

The onset of drug-induced TdP is variable, particularly when it is associated with oral drug therapy. TdP associated with intravenous drug therapy usually coincides with the expected time of peak concentration of the causative agent. For example, many of the cases of TdP induced by intravenous erythromycin occurred during the infusion or within 30 minutes of completion of the infusion.[350,352,355,360,362,370] TdP induced by intravenous haloperidol occurs within 15–220 minutes after the infusion.[409] Ibutilide-induced TdP occurs within 2–60 minutes after drug administration, but most often within 15 minutes.[124-126,128,417-425]

TdP induced by oral drugs may be delayed. In an analysis of 144 published articles describing 249 patients who experienced TdP associated with noncardiac drugs, only 18% of the cases occurred within 72 hours of the initiation of oral therapy; 42% occurred between 3 and 30 days after the initiation of therapy, and 40% occurred more than 30 days after the initiation of therapy.[688]

Conditions to consider in the differential diagnosis of drug-induced TdP are listed in **Table 25-10**. Other tachyarrhythmias must be excluded, through review of the ECG. If the patient has polymorphic ventricular tachycardia, TdP must be distinguished from non-TdP polymorphic ventricular tachycardia; this can be achieved by determining whether prolongation of the QTc interval is present prior to or shortly after the episode of polymorphic ventricular tachycardia. The patient's list of current medications should be reviewed to determine whether he or she is receiving a drug that has been reported to cause TdP, or at least to cause QTc interval prolongation. In addition, the patient should be evaluated for the presence of concomitant risk factors for TdP, which substantially increase the likelihood of the occurrence of the tachyarrhythmia.

Table 25-10 Conditions to Consider in the Differential Diagnosis of Drug-Induced Torsades de Pointes

- Atrial fibrillation
- Atrial flutter
- Atrial tachycardia

- Atrioventricular nodal re-entrant tachycardia
- Idioventricular tachycardia
- Non-TdP polymorphic ventricular tachycardia
- Sinus tachycardia
- Junctional tachycardia
- Monomorphic ventricular tachycardia
- Ventricular fibrillation

TdP = torsades de pointes.

Table 25-11 Risk Factors for Drug-Induced Torsades de Pointes

- Advanced age
- Bradycardia
- Concomitant administration of >1 agent known to cause QTc interval prolongation or TdP
- Elevated plasma concentrations of QT interval-prolonging drugs due to drug interactions or inadequate dose adjustment for organ dysfunction
- Female sex
- HFrEF
- History of drug-induced TdP
- Hypocalcemia
- Hypokalemia
- Hypomagnesemia
- Increase in QTc interval by >60 msec compared with the pretreatment value
- QTc interval >500 msec
- Rapid intravenous infusion of QTc interval-prolonging drugs
- Sepsis

HFrEF = heart failure with reduced ejection fraction, TdP = torsades de pointes.

RISK FACTORS

Specific risk factors for drug-induced TdP have been identified (**Table 25-11**). Prolongation of the QTc interval on the ECG has consistently been determined to be a risk factor. Evidence indicates that the risk of TdP increases markedly when the QTc interval becomes prolonged to >500 msec, and TdP is rare when the QTc interval is <500 msec.[409,689-691] The risk of TdP is also increased when the QTc interval increases >60 msec compared with pretreatment values.[690] Other TdP risk factors include female sex, advanced age, bradycardia, hypokalemia, hypomagnesemia, hypocalcemia, HFrEF, and conditions leading to elevated plasma concentrations of causative drugs, such as kidney disease, liver disease, drug interactions, or some combination of these.[195,196,691,692] A history of drug-induced TdP likely increases the risk for TdP associated with other QT interval-prolonging drugs.[195,215]

Drug-induced TdP is exceedingly rare in patients without concomitant risk factors. An analysis of 144 published articles describing 249 patients who experienced TdP associated with noncardiac drugs revealed that nearly 100% of the patients had at least one risk factor, and 71% of the patients had at least two risk factors.[688] More than two thirds of the patients were female; 41% had heart disease (defined as myocardial infarction, heart failure, valvulopathy, or cardiomyopathy); 28% had hypokalemia; 19% had drug toxicity (defined as administration of higher-than-recommended doses or lack of dose adjustment for organ dysfunction); 18% had a familial history of long-QT syndrome, a history of previous drug-induced TdP, or a history of drug-induced QTc interval prolongation.[688] Drug interactions leading to increased plasma concentrations of the causative agent were present in 35% of the patients. These data indicate that the vast majority of patients who develop noncardiac drug-induced TdP have risk factors that are easily identifiable.

Explanations for an increased risk of drug-induced TdP in specific patient populations continue to be investigated.[693] Reasons that women are at increased risk for drug-induced TdP may involve arrhythmogenic effects of estrogen in women or protective effects of testosterone in men.[694,695] The baseline QTc interval is longer in women than in men, a difference that manifests at puberty.[696,697] In one series of 332 cases of TdP associated with antiarrhythmic agents, 70% of the cases occurred in women.[698] Other studies have documented a female predisposition to TdP associated with azimilide, dofetilide, erythromycin, ibutilide, quinidine, sotalol, and terfenadine.[333,551,691,699-702] The influence of sex hormones on ventricular repolarization and risk for TdP has been investigated and remains a subject of ongoing study. One group of investigators administered a small dose of intravenous ibutilide to healthy women during three phases of the menstrual cycle and attempted to correlate plasma concentrations of estradiol and progesterone with ibutilide-induced prolongations in the QTc interval. QTc interval prolongation was not correlated with plasma estradiol concentration but was inversely correlated with the plasma progesterone concentration and the plasma progesterone-to-estradiol ratio, suggesting that estrogen may not be proarrhythmic, but that progesterone, an androgenic compound, may be protective against drug-induced QTc interval lengthening.[703] In vitro studies have shown that dihydrotestosterone shortens basal action potential duration and diminishes the effects of potassium channel-blocking drugs on action potential duration.[704] Therefore, androgens may protect against the electrophysiologic effects of drugs with the potential to induce TdP.

HFrEF is a major risk factor for drug-induced TdP. The incidence of TdP associated with drugs such as ibutilide and dofetilide has been shown to be more than twice as high in patients with HFrEF than in patients with normal left ventricular function.[324,325,418,419] Mechanisms behind the increased risk of TdP in this population are unclear. Downregulation of potassium channels occurs in patients with HFrEF, promoting prolongation in ventricular repolarization. Patients with HFrEF have been shown to be more sensitive to drug-induced QTc interval lengthening than those with normal left ventricular function.[705,706] In a study of ibutilide pretreatment for facilitation of direct current cardioversion of atrial fibrillation, two of 64 ibutilide-treated patients (3.1%) had TdP; both patients had a left ventricular ejection fraction <20%.[422] On the basis of this study, many recommend that QTc interval-prolonging drugs should not be administered to patients with a left ventricular ejection fraction <20%. It remains unknown whether heart failure with preserved ejection fraction is a risk factor for drug-induced TdP.

Elevated plasma concentrations of drugs known to cause TdP are an important risk factor. The majority of cases of TdP associated with erythromycin or haloperidol occurred after intravenous administration of the drug, possibly as a result of higher peak plasma concentrations.[350,352,355,359,362,365,366,370,404-407,409-412] In addition, failure to adequately adjust specific drug doses for kidney disease has resulted in TdP associated with dofetilide, levofloxacin, procainamide, and sotalol.[431,504,546,547,552,553,707] Drugs that have been reported to cause TdP that require dose adjustment in patients with kidney disease or hepatic impairment are listed in **Tables 25-12** and **25-13**, respectively.

Table 25-12 Drugs That May Induce Torsades de Pointes and Require Dose Adjustment or Are Contraindicated in Patients with Kidney Disease

- Amantadine
- Amisulpride
- Arsenic trioxide
- Chloral hydrate
- Ciprofloxacin
- Clarithromycin
- Disopyramide
- Dofetilide
- Domperidone
- Famotidine
- Flecainide
- Fluconazole
- Gatifloxacin
- Levofloxacin
- Loratadine
- Metoclopramide
- Ofloxacin
- Oxaliplatin
- Pentamidine
- Posaconazole
- Procainamide
- Quinidine
- Quinine
- Risperidone
- Solifenacin
- Sotalol
- Sparfloxacin

- Tacrolimus
- Vandetanib

Table 25-13 Drugs That May Induce Torsades de Pointes and Require Dose Adjustment or Are Contraindicated in Patients with Liver Disease

- Atazanavir
- Buprenorphine
- Cisapride
- Citalopram
- Domperidone
- Dronedarone
- Escitalopram
- Fluoxetine
- Itraconazole
- Ivabradine
- Levomepromazine
- Metronidazole
- Nelfinavir
- Olanzapine
- Ondansetron
- Quetiapine
- Quinidine
- Ranolazine
- Risperidone
- Roxithromycin
- Solifenacin
- Tacrolimus
- Voriconazole
- Vorinostat

Drug interactions are a particularly important risk factor for drug-induced TdP. Of 25 cases of TdP associated with terfenadine that were reported to the U.S. Food and Drug Administration (FDA), nine patients were receiving concomitant therapy with ketoconazole or itraconazole, which inhibit the metabolism of terfenadine.[702] Numerous reported cases of drug-induced TdP occurred as a result of drug interactions leading to elevated plasma concentrations of the offending agent.[213,277,281,284,296,299,347,358,363,369,371] Drugs associated with a risk of TdP that are substrates for the cytochrome P-450 system, and therefore subject to drug interactions when used in combination with inhibitors of enzymes of the cytochrome P-450 system, are listed in **Table 25-14**.[708]

Bradycardia has been shown to be a risk factor for drug-induced TdP. Ventricular repolarization is dependent on heart rate; the slower the heart rate, the longer the period of ventricular repolarization.[680] The majority of drugs with the potential to cause TdP to bind to potassium channels in a manner called reverse-use-dependent (which means that the slower the heart rate, the more tightly the drug binds to the potassium channel) likely explains the higher risk of TdP at slower heart rates.[709]

Use of combinations of QT interval-prolonging drugs may increase the risk for drug-induced TdP, although conflicting data exist. Polypharmacy with QT interval-prolonging drugs and/or with interacting drugs is common. A retrospective cohort study of an outpatient prescription claims database revealed that 9.4% of approximately 1.1 million patients who filled a prescription for a QT interval-prolonging drug also filled an overlapping prescription for a second QT interval-prolonging drug or for a drug known to inhibit the clearance of the QT interval-prolonging agent.[710] In a similar study, automated drug-dispensing data from 2 million health plan members from a total of 10 health maintenance organizations were reviewed to determine the proportion of these patients who had been prescribed QT interval-prolonging drugs, and the proportion of those patients for whom a second QT interval-prolonging drug or a drug known to alter the clearance of the QT interval-prolonging medication was prescribed.[711] Of the patients from whom data were obtained, 11.4% had received prescriptions for a potentially QT interval-prolonging drug. Of the patients who received prescriptions for a QT interval-prolonging drug, 4.6% also received a prescription for a potentially interacting drug that could increase the risk of TdP.[711] Approximately 15% of emergency department visits involve prescriptions of a QT interval-prolonging drug, roughly 10% of which involved prescriptions for ≥2 QT interval-prolonging agents.[712] Therefore, concomitant use of multiple QT interval-prolonging drugs is relatively common. Some evidence indicates that this practice increases the risk of QT interval prolongation and/or TdP. In an analysis of patients in cardiac critical care units, use of ≥2 QT interval-prolonging drugs was associated with an odds ratio for development of QTc interval prolongation of 2.6 (95% CI 1.9–5.6, p = 0.02).[692] However, other data do not indicate that combinations of QT interval-prolonging drugs increase the risk of QTc interval prolongation or TdP compared with therapy with a single QTc interval-prolonging agent. A systematic review of literature regarding antipsychotic therapy concluded that antipsychotic polypharmacy may not worsen QTc interval prolongation.[713] In a population-based cohort study of approximately 13,000 patients, the addition of a second or third QTc interval-prolonging drug to initial QTc interval-lengthening therapy exerted only a very small additional effect on QTc interval.[714] Further study is needed to ascertain the safety of use of combinations of QTc interval-prolonging drugs.

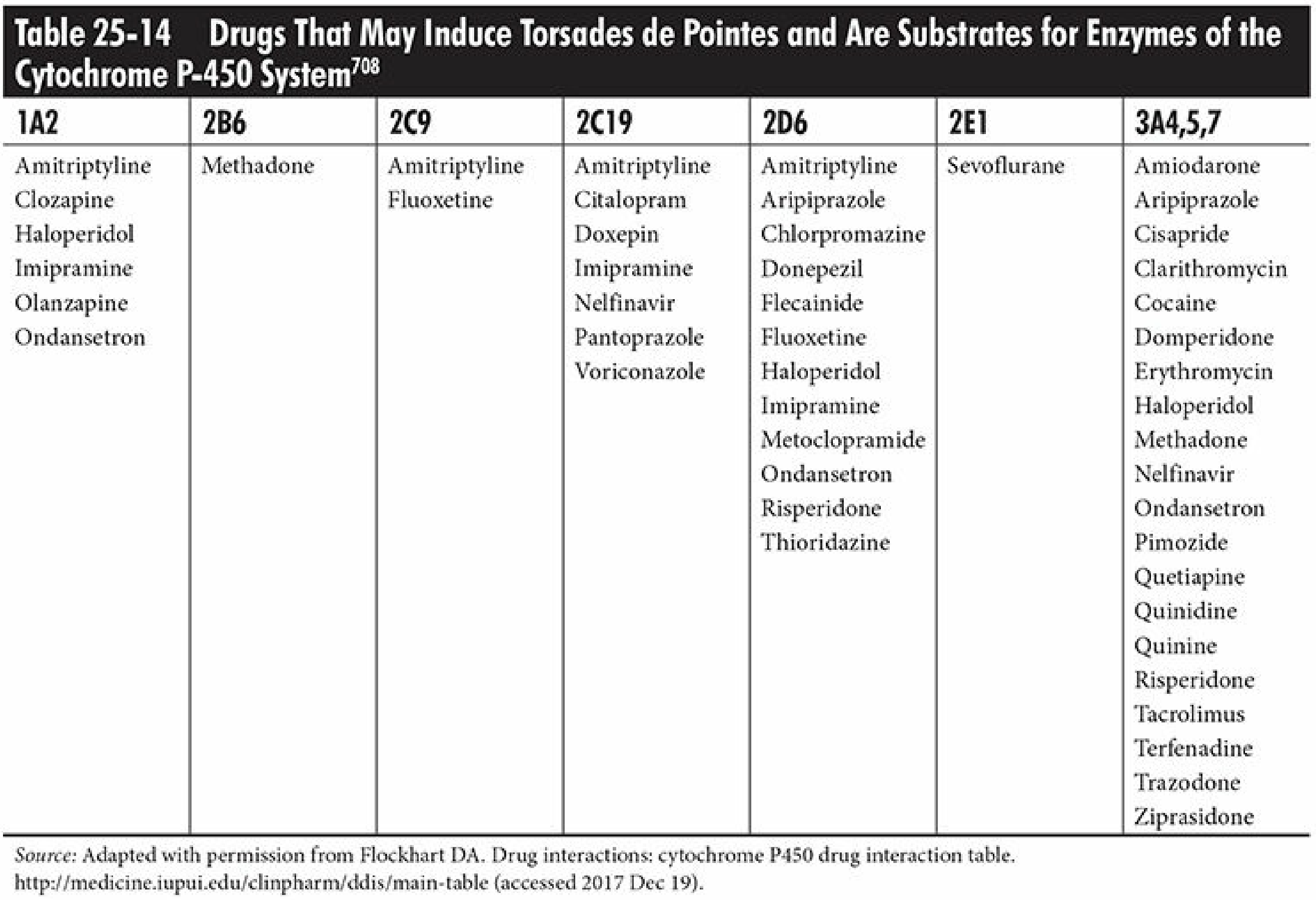

Table 25-14 Drugs That May Induce Torsades de Pointes and Are Substrates for Enzymes of the Cytochrome P-450 System[708]

Some evidence suggests that patients in whom drug-induced TdP develops may have a genetic predisposition. Fifteen specific genetic defects have been identified that underlie the congenital long-QT interval syndromes.[715] Mutations of genes that are known to predispose to the congenital long-QT interval syndromes were shown to be present in 10–15% of patients who experience drug-induced TdP.[716] In another study, missense mutations in five long QT-interval genes were found in a small minority of patients with drug-induced TdP.[717] Itoh et al.[718] reported that 40% of 20 patients with drug-induced TdP had mutations in long-QT syndrome genes and that the incidence of mutations was higher in patients with TdP induced by nonantiarrhythmic drugs compared to antiarrhythmic drugs. The positive mutation rate in patients with drug-induced TdP was similar to that in patients with congenital long-QT syndrome. However, results from a genome-wide association study suggest that genetic polymorphisms may not contribute importantly to the risk of drug-induced TdP.[719] This study included 216 patients with TdP from Northwestern Europe and in 771 ancestry-matched controls, including treatment-tolerant patients and individuals in the general population. No single nucleotide polymorphism reached genome-wide significance, suggesting that common genomic variants do not contribute importantly to the risk of drug-induced TdP.[719]

MORBIDITY AND MORTALITY

TdP may result in clinical symptoms requiring medical attention. More importantly, TdP may result in sudden cardiac death; the incidence of sudden death due to TdP is unknown. During the past couple of decades, a number of drugs, including terfenadine, astemizole, grepafloxacin, cisapride, levomethadyl, and mesoridazine, have been removed from the U.S. market as a result of causing deaths due to TdP.

In a retrospective analysis of 205 patients with advanced HFrEF, patients with a history of drug-induced TdP had a significantly higher risk of sudden cardiac death during therapy with amiodarone as compared with amiodarone-treated patients with no history of drug-induced TdP (55% versus 15%).[720] These data suggest that drugs known to prolong the QT interval should not be administered to patients with advanced HFrEF and a history of drug-induced TdP.

Antipsychotic agents have been associated with an increased risk of sudden cardiac death, potentially as a result of TdP. The risk of sudden cardiac death associated with antipsychotic drugs was investigated in a population-based case–control study of a longitudinal database consisting of medical records from 150 general practitioners in Europe.[721] Current use of antipsychotic agents was associated with a significant increase in the risk of sudden cardiac death (OR 3.3, 95% CI 1.8–6.2). Previous use of antipsychotic drugs was not associated with an increased risk of sudden cardiac death. The risk of sudden cardiac death was highest among patients receiving butyrophenone agents (such as haloperidol).[721] The precise cause of sudden cardiac death was not documented in this study, but these drugs are known to be a cause of TdP, which may have contributed to sudden cardiac death in these patients. A retrospective cohort study of Medicaid enrollees in Tennessee also reported an increased risk of sudden cardiac death associated with both typical and atypical antipsychotic drugs.[722] In a retrospective cohort study from a large database, the adjusted relative risk of cardiac mortality associated with olanzapine was significantly elevated compared to psychiatric nonusers of olanzapine (RR 1.53, 95% CI 1.12–20.9).[723] Treatment with any antipsychotic agent and with typical antipsychotic agents was associated with significantly increased risks of out-of-hospital cardiac arrest in a study of the Danish Cardiac Arrest Register.[724] In a case-crossover study conducted using the Taiwan National Health Insurance Research Database, antipsychotic drug use was associated with a significantly increased risk of ventricular arrhythmia and/or sudden cardiac death, and antipsychotic agents with the greatest potency to inhibit I_{Kr} were associated with the highest risk of ventricular arrhythmias and/or sudden cardiac death.[725] A meta-analysis of observational studies assessing the influence of antipsychotic agents on sudden cardiac death concluded that the risk differed among different antipsychotics (thioridazine>clozapine>risperidone>haloperidol>olanzapine>quetiapine).[726]

Macrolide antibiotics have also been associated with an increased risk of sudden cardiac death. In a study of a cohort of patients identified from the

Tennessee Medicaid database, the multivariate-adjusted rate of sudden death from cardiac causes was twice as high in patients currently using erythromycin as compared with that in patients who had not used the drug.[727] Further, the adjusted rate of sudden death from cardiac causes was five times higher among patients who had concurrently used drugs that inhibited activity of the cytochrome P-450 enzyme system while taking erythromycin.[727] These data indicate that erythromycin use, particularly in combination with potentially interacting drugs, may markedly increase the risk of cardiac mortality. A similar study of the Tennessee Medicaid database found that patients taking 5 days of therapy with azithromycin had an increased risk of cardiovascular death (HR 2.88, 95% CI 1.79–4.63, $p < 0.001$) and death from any cause (HR 1.85, 95% CI 1.25–2.75, $p = 0.002$) compared to patients who took no antibiotics.[728] Compared to patients taking amoxicillin, those who took azithromycin for 5 days had an increased risk of cardiovascular death (HR 2.49; 95% CI 1.38–4.50, $p = 0.002$) and death from any cause (HR 2.02, 95% CI 1.24–3.30, $p = 0.005$).[728] Similarly, in a cohort study of U.S. veterans, patients receiving 5 days of azithromycin therapy had an increased risk of death (HR 1.48, 95% CI 1.05–2.09) and serious arrhythmia (HR 1.77, 95% CI 1.20–2.62) compared with patients receiving amoxicillin.[729] Clarithromycin was associated with an increased risk of cardiovascular events (defined as hospital admissions with acute coronary syndrome, decompensated heart failure, serious arrhythmia, or sudden cardiac death) in a propensity score-matched study of two prospectively collected datasets in patients with chronic obstructive pulmonary disease.[730] Conversely, however, a propensity score-matched nationwide historical cohort study of the Danish Civil Registration System found that current azithromycin use was not associated with an increased risk of cardiovascular death compared to penicillin V (rate ratio 0.93, 95% CI 0.56–1.55).[731] Cheng et al.[732] performed a meta-analysis of 33 studies involving nearly 21 million patients to assess the association between macrolide antibiotics and cardiovascular risk. Compared to those not taking macrolides, patients taking macrolides had an increased risk of sudden cardiac death or ventricular tachyarrhythmias (RR 2.42 [1.61–3.63]), sudden cardiac death (2.52 [1.91–3.31]), and cardiovascular death (1.31 [1.06–1.62]). The weight of the overall data suggests that macrolide antibiotics are associated with an increased risk of sudden cardiac death and cardiovascular death.

An analysis was performed of reports to the FDA of QTc interval prolongation and TdP associated with methadone.[443] From 1969 through October 2002, the FDA received 43 reports of TdP and 15 reports of QTc interval prolongation. Hospitalization was required in 47% of these cases, and death occurred in 8%.

In summary, drug-induced TdP may result in morbidity requiring hospitalization and mortality due to sudden cardiac death. Patients with a history of drug-induced TdP and those currently receiving typical or atypical antipsychotic agents or macrolide antibiotics have been shown to be at higher risk of cardiovascular mortality.

PREVENTION

Some methods of prevention of drug-induced TdP are listed in **Table 25-15**. Drug-induced TdP may be prevented by minimizing risk factors associated with TdP (Table 25-11). Intravenous erythromycin doses of 1 g every 6 hours should be avoided, unless *Legionella pneumophila* infection is documented. The maximum daily dose of intravenous haloperidol should not exceed 35 mg.[409]

In patients receiving drugs known to promote the development of TdP, the QTc interval should be monitored and maintained at <500 msec. Prior to initiating therapy with a drug known to cause TdP, a baseline (predrug) ECG for determination of QTc interval should be obtained wherever possible. In hospitalized patients receiving drugs known to cause TdP, QTc intervals should be monitored daily, preferably using a 12-lead ECG but at least using a lead II ECG strip. Some hospitals have the capability for fully automated QTc interval monitoring, with which an algorithm measures the QTc interval every 5 minutes, and an audible alarm sounds if there is an increase in QTc interval >60 msec from baseline or if a QTc interval >500 msec is measured for at least three consecutive measurements (i.e., 15 minutes).[686] Patients receiving long-term oral therapy with drugs known to promote the development of TdP should undergo a 12-lead ECG for the measurement of QTc intervals every 3 to 6 months depending on the presence or absence of other risk factors.

Clinical decision support tools have been developed with the objective of reducing the risk of TdP. At the Mayo Clinic, an institution-wide computer-based QT interval alert system was implemented, which screens all ECGs and alerts physicians if their patient’s QTc interval is ≥500 msec.[733] Sorita et al.[734] developed and implemented a clinical decision support system integrated into the computerized physician order-entry system that identifies any attempt to order medications associated with TdP for patients with a history of QTc interval ≥500 msec and alerts the provider entering the order. This system resulted in a 13.9% reduction in administration of potentially TdP-inducing drugs to these high-risk patients. Another group of investigators developed and implemented a clinical decision support computer alert incorporating a validated risk score for QTc interval prolongation for patients in cardiac critical care units.[692,735] In this system, the computer calculates each patient’s risk score for development of QTc interval prolongation. When patients are prescribed a drug with the potential to induce TdP and their QTc interval prolongation risk score is moderate or high (but not low), a computer alert appears to the pharmacist entering or reviewing the order, who can then contact the prescriber to discuss modulation of modifiable risk factors or selection of alternate drug therapy, where appropriate. Implementation of this computer alert system resulted in a significant reduction in the risk of QTc interval prolongation in these units (OR 0.65, 95% CI 0.56–0.89, *p* <0.0001). In addition, implementation of this alert system resulted in a significant reduction in the prescribing of noncardiovascular QTc interval-prolonging drugs.[735]

Table 25-15 Prevention of Drug-Induced Torsades de Pointes

- Adjust doses of renally eliminated QTc interval-prolonging drugs in patients with kidney disease
- Adjust doses or avoid use of hepatically metabolized QTc interval-prolonging drugs in patients with liver disease
- Avoid concomitant administration of QTc interval-prolonging drugs
- Avoid drug interactions involving QTc interval-prolonging drugs that are substrates of the cytochrome P-450 enzyme system with cytochrome P-450 enzyme inhibitors
- Avoid use of QTc interval-prolonging drugs in patients who have been diagnosed with one of the congenital long QT interval syndromes
- Avoid use of QTc interval-prolonging drugs in patients with a history of drug-induced TdP
- Avoid use of QTc interval-prolonging drugs in patients with pretreatment QTc intervals >450 msec
- Discontinue QTc interval-prolonging agent if QTc increases to >500 msec
- Maintain serum calcium concentrations within normal range
- Maintain serum magnesium concentrations ≥2 mg/dL
- Maintain serum potassium concentrations ≥4 mEq/L
- Reduce dose or discontinue QTc interval-prolonging agent if QTc increases >60 msec from pretreatment value
- When possible, avoid use of QTc interval-prolonging drugs in patients with HFrEF, especially in patients with LVEF <20%

HFrEF = heart failure with reduced ejection fraction, TdP = torsades de pointes.

Although drugs with the potential to cause TdP should not necessarily be avoided in female patients, other risk factors associated with drug-induced TdP are easily identifiable prior to the initiation of therapy with QTc interval-prolonging drugs, and use of QTc interval-prolonging drugs in patients with these other risk factors should be avoided whenever possible.[688,692] In particular, concomitant administration of susceptible QT interval-prolonging drugs with drugs that inhibit their metabolism should be avoided, and doses of renally eliminated or hepatically metabolized QTc interval-prolonging drugs should be adequately adjusted in patients with kidney or liver disease, respectively.

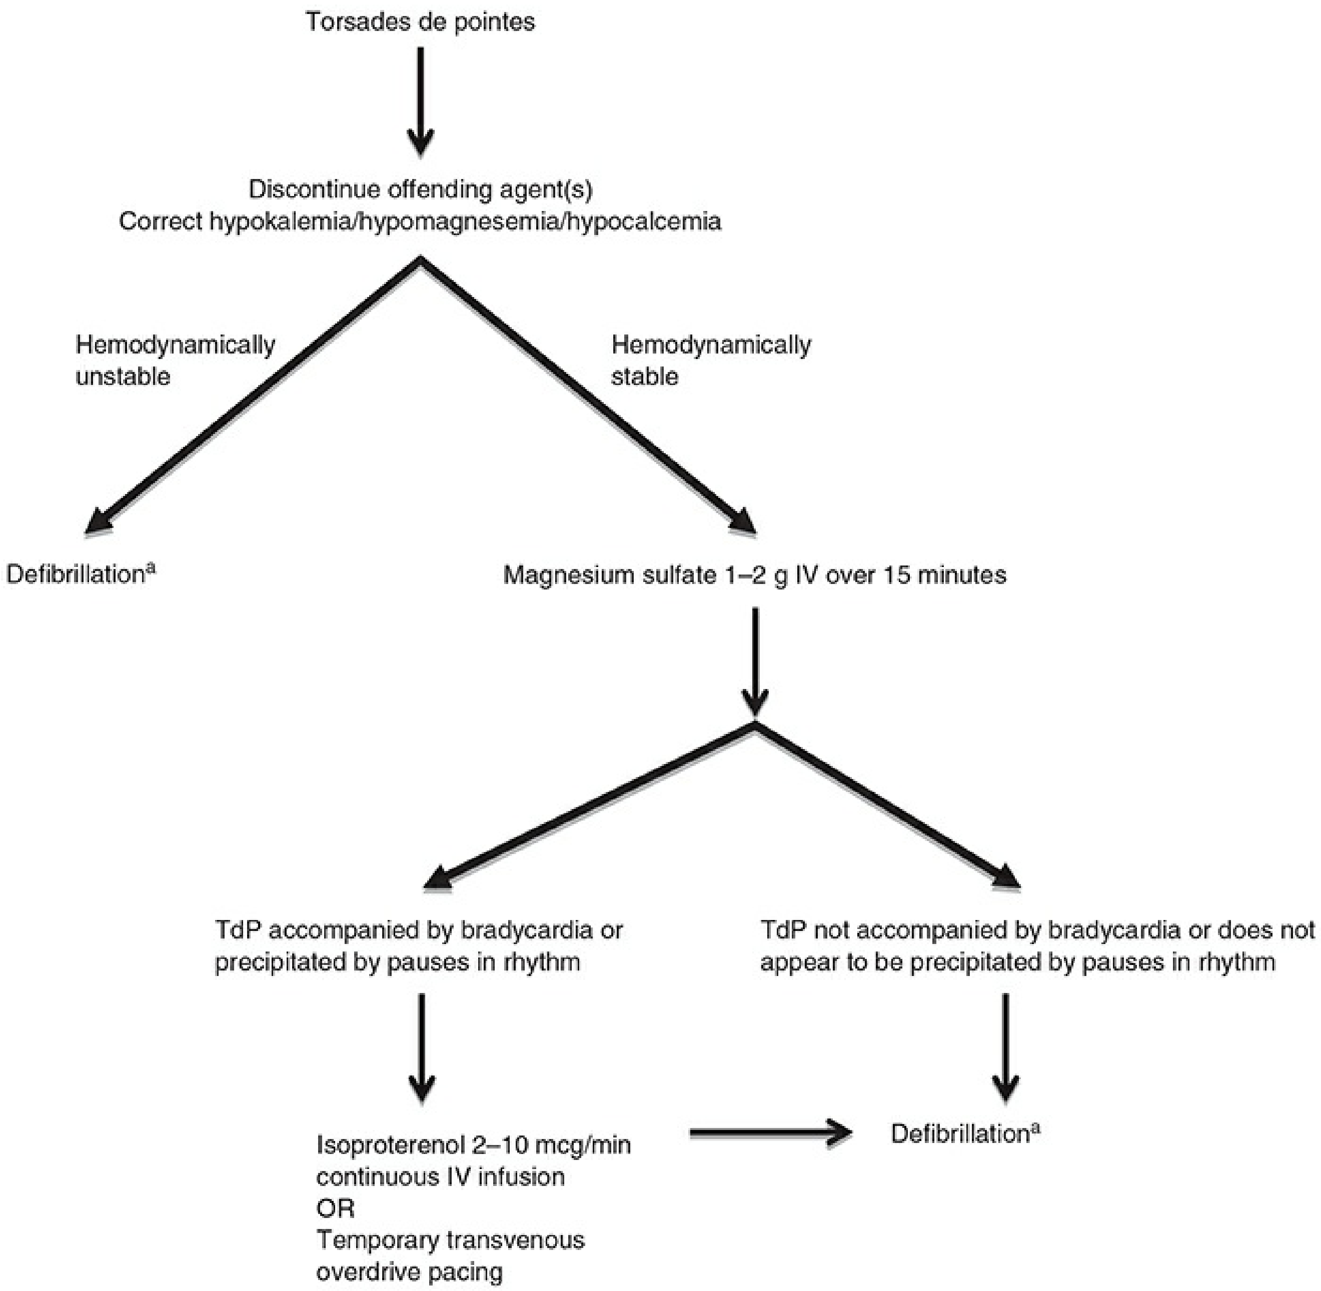
Prophylactic administration of magnesium has been shown to attenuate the effects of drugs on QT interval prolongation. Administration of magnesium sulfate 2 g intravenously prior to administration of ibutilide 1 mg significantly diminished the effect of ibutilide on QT interval prolongation in patients with normal serum magnesium concentrations compared with that in a group of normomagnesemic patients who received placebo prior to ibutilide. In addition, pretreatment with magnesium significantly reduced the risk of ibutilide-induced QT interval prolongation >30 msec as compared with preibutilide values.[736] Patsilinakos et al.[131] retrospectively analyzed 476 patients who had received ibutilide for conversion of atrial fibrillation or atrial flutter to sinus rhythm during a 4-year period. All patients received ibutilide 1 mg intravenously over 10 minutes, followed by a second 1-mg dose if necessary 10 minutes following completion of the first infusion. In $n = 247$ patients, a 1-hour intravenous infusion of magnesium 5 g was administered prior to ibutilide, followed by a second infusion of magnesium 5 g, this time over 2 hours, without interrupting the ibutilide infusion protocol. The incidence of TdP was significantly lower in the patients who received magnesium prophylaxis compared to those that did not (0% versus 3.5%, $p = 0.009$). The incidence of all ventricular arrhythmias (sustained ventricular tachycardia, nonsustained ventricular tachycardia, and TdP) was also significantly lower in the magnesium prophylaxis group (1.2% versus 7.4%, $p = 0.002$). The two groups were similar demographically, although those in the magnesium prophylaxis group were slightly older (62 versus 58 years, $p = 0.057$). These data suggest that magnesium prophylaxis may be a reasonable strategy in patients at risk for TdP who require ibutilide therapy for atrial fibrillation or atrial flutter.

In a prospective, randomized, double-blind, placebo-controlled crossover pilot study, administration of oral progesterone 400 mg daily was found to attenuate drug-induced QTc interval lengthening in young healthy women during the menses phase of the menstrual cycle (when endogenous serum progesterone concentrations are lowest).[737] Studies are ongoing to determine whether exogenous administration of sex hormones may reduce the risk of drug-induced QTc interval prolongation in patient populations at risk.

Specific guidelines were published regarding monitoring of patients for prevention of methadone-induced TdP.[738] These guidelines recommend that all patients on methadone therapy should undergo a pretreatment ECG for determination of the QTc interval, a follow-up 12-lead ECG for determination of the QTc interval within 30 days of the initiation of methadone treatment, and a 12-lead ECG for QTc interval determination annually. More intensive QTc interval monitoring was recommended for patients who require daily methadone doses >100 mg and for those that experience unexplained syncope or seizures. Subsequent recommendations tempered the 30-day ECG suggestion on the basis of concerns regarding the resources required to implement routine ECGs and the absence of strong evidence that such routine ECG monitoring reduces the incidence of methadone-associated cardiac events.[739] These newer recommendations suggested that a baseline ECG should be performed at the time of admission into an opioid treatment program and within 30 days in patients with significant risk factors for QTc interval prolongation, and that additional ECGs should be performed annually or whenever the methadone dose exceeds 120 mg daily.[739]

MANAGEMENT

A treatment strategy for the acute management of drug-induced TdP is presented in **Figure 25-4**.[190] Management of drug-induced TdP is dependent on recognition of the arrhythmia and distinguishing it from monomorphic ventricular tachycardia or non-torsades polymorphic ventricular tachycardia. Therapy with drugs with the potential to cause TdP should be discontinued. Hypokalemia, hypomagnesemia, or hypocalcemia should be corrected with intravenous potassium, magnesium, or calcium, respectively. Patients with TdP who are hemodynamically unstable should be treated with asynchronous shocks (i.e., defibrillation).[190] Although synchronized direct current cardioversion is preferred for organized rhythms, synchronization of shocks is often not possible in patients with polymorphic ventricular tachycardias such as TdP, because the multiple QRS complex configurations and fluctuating heart rates render it very difficult, and sometimes impossible, to synchronize the delivery of the shock to a QRS complex.[190]



Torsades de pointes
Discontinue offending agent(s)
Correct hypokalemia/hypomagnesemia/hypocalcemia
Hemodynamically unstable
Hemodynamically stable
Defibrillation^a
Magnesium sulfate 1–2 g IV over 15 minutes
TdP accompanied by bradycardia or precipitated by pauses in rhythm
TdP not accompanied by bradycardia or does not appear to be precipitated by pauses in rhythm
Isoproterenol 2–10 mcg/min continuous IV infusion
OR
Temporary transvenous overdrive pacing
Defibrillation^a

Several treatment options are available for patients with hemodynamically stable TdP (Figure 25-4). Intravenous magnesium has been reported to terminate TdP, irrespective of the patient's serum magnesium concentration.[199,290,458,508,521,548,561,740-747] The mechanism by which intravenous magnesium terminates TdP is not clear, but termination may occur via inhibition of early afterdepolarizations as a result of calcium-channel blockade.

Overdrive pacing via the percutaneous insertion of a temporary pacemaker is also effective for termination of TdP accompanied by bradycardia or precipitated by pauses in rhythm, as overdrive pacing leads to shortening of the QT interval.[190,312,501,536] Intravenous isoproterenol may also terminate TdP, by increasing heart rate and shortening the QT interval.[190,191,507,748] In addition, refractory TdP associated with sotalol has been successfully managed using hemodialysis or peritoneal dialysis.[547,554,555]

INFORMATION FOR PATIENTS

Patients who are taking drugs that may cause TdP should be instructed that the drug may in rare cases cause the heart rate (pulse) to become faster. Patients should be instructed to consult their pharmacist or physician if the heart rate increases to above 100–120 bpm, or if they feel palpitations, lightheaded, dizzy, tired, weak, short of breath, or chest pain. Patients who are taking drugs that may cause TdP should be instructed not to take any nonprescription medication without first consulting their pharmacist or physician because of the possibility of interactions of potentially proarrhythmic medications with nonprescription drugs such as cimetidine. In addition, patients should make sure that their pharmacist and physician are fully aware of all medications that they are taking to avoid receiving new medications that may potentially interact with drugs that may cause TdP.

BRUGADA SYNDROME

Brugada syndrome is an inherited disorder characterized by specific ECG abnormalities not associated with myocardial ischemia, electrolyte perturbations, or structural heart disease.[749] Brugada syndrome is classified into three types, based on specific ECG abnormalities in at least two of the right chest leads (V_1–V_3): Type 1—coved ST segment elevation, J point elevation ≥2 mm, and inverted T wave; Type 2—saddle-shaped ST segments with J point elevation ≥2 mm and ST segment elevation ≥1 mm with a positive or biphasic T wave; and Type 3—saddle-shaped ST segments with J point elevation <2 mm and ST segment elevation <1 mm. In addition to the ECG abnormalities, diagnostic criteria include syncope, prior cardiac arrest, documented or inducible polymorphic ventricular tachycardia or ventricular fibrillation, a family history of sudden death <45 years of age, or Type 1 Brugada pattern and/or nocturnal agonal respiration.[750]

In the majority of cases, Brugada syndrome is caused by mutations in the gene *SCN5A*, which encodes cardiac sodium channels. Sodium channel-blocking drugs such as flecainide are often used to unmask concealed forms of the Brugada syndrome. However, a drug-induced form of Brugada syndrome has been described, in which drugs provoke Brugada syndrome ECG patterns and cause ventricular tachycardia, ventricular fibrillation, and sudden cardiac death.

CAUSATIVE AGENTS

Drugs that have been reported to exacerbate or provoke Brugada syndrome are presented in **Table 25-16**.[749,751-786] Up-to-date lists of drugs associated with Brugada syndrome may be found at Brugadadrugs.org.[787] Drugs in Table 25-16 are those with published literature supporting an association with arrhythmias and the most typical (Type 1) Brugada syndrome ECG. A list of drugs that are recommended to be avoided in patients with Brugada syndrome, but for which there is no published evidence of an association with arrhythmias, can be found at Brugadadrugs.org.[787]

EPIDEMIOLOGY

The prevalence of the Brugada syndrome is estimated to be 1–5 per 10,000 persons.[788] The prevalence is higher in countries in Southeast Asia, especially Thailand, the Philippines, and Japan, where the prevalence is roughly 0.5–1 per 1,000 persons.[750] The prevalence of Brugada syndrome is 8–10-fold higher in men than women.[788,789] The higher prevalence in males may be due to more prominent transient outward potassium current (I_{to}) and/or higher plasma testosterone concenrations.[790,791]

The overall incidence and prevalence of drug-induced Brugada syndrome are not known, and the incidence has been determined for only a small number of drugs known to exacerbate this syndrome (Table 25-16).

MECHANISMS

Brugada syndrome is inherited via autosomal dominance (with the exception of one genotype, which is inherited in an X-linked manner).[789,792] To date, 23 genotypes have been identified, which are associated with a decrease in inward sodium or calcium current or an increase in outward potassium current.[792] One genotype, caused by pathogenic variants in the *SCN5A* gene that encodes for the α subunit of the cardiac sodium channel, is responsible for 15–30% of patients with the Brugada syndrome.[789,792] The precise mechanism of the ECG abnormailities and arrhythmias associated with the Brugada syndrome is unknown. It has been proposed that the ST segment elevation associated with Brugada syndrome may be due to local conduction abnormalities, local ventricular depolarization, or an early repolarization abnormality caused by reduction in fast sodium current and/or L-type calcium current or an increase in I_{to}, which would result in shortening of the epicardial action potential.[793,794] This would produce increased dispersion of repolarization across the epicardium/endocardium. Increased dispersion of ventricular repolarization in association with extrasystoles may lead to re-entrant arrhythmias.[749] Drugs that provoke or unmask the Brugada syndrome are predominantly those that inhibit cardiac sodium channels (Table 25-16).[749,795] The mechanism of alcohol-induced Brugada syndrome is not clear, although it has been suggested that alcohol-associated enhancement of parasympathetic nervous system activity may contribute.[758]

Table 25-16 Agents Implicated in Drug-Induced Brugada Syndrome

Drug	Incidence	Level of Evidence[a]
Ajmaline[751-756]	0.15–1.8% (adults) 10% (children)	B
Alcohol[757-759]	NK	C
Amitriptyline[760,761]	NK	C
Bupivacaine[762]	NK	C
Cocaine[763-765]	NK	C
Desipramine[766]	NK	C
Flecainide[767-769]	NK	C
Lithium[770]	NK	C
Loxapine[771]	NK	C
Nortriptyline[772,773]	NK	C
Oxcarbazepine[774]	NK	C
Pilsicainide[775-779]	11–18%	B
Procainamide[780]	NK	C
Propafenone[781,782]	NK	C
Propofol[783-786]	NK	C
Trifluoperazine[771]	NK	C

NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials;

Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

Table 25-17 Signs and Symptoms Associated with Drug-Induced Brugada Syndrome

- Aborted sudden cardiac death
- Chest discomfort
- Idioventricular tachycardia
- Monomorphic ventricular tachycardia
- Nocturnal agonal respiration
- Palpitations
- Syncope
- Ventricular fibrillation

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Clinical symptoms associated with drug-induced Brugada syndrome are presented in **Table 25-17**. Drug-induced Brugada syndrome manifests in relatively young individuals. In a study of the clinical characteristics and risk factors for drug-induced Brugada syndrome, the mean age of onset was 39 ± 16 years.[795] In this study, 77% of patients who developed the drug-induced Brugada syndrome ECG pattern were male, and men developed the syndrome at a younger age than women (37 ± 16 years versus 44 ± 17 years, $p = 0.07$). Symptoms associated with drug-induced Brugada syndrome include monomorphic ventricular tachycardia, idioventricular tachycardia, ventricular fibrillation or aborted sudden cardiac death, syncope, nocturnal agonal respiration, palpitations, and chest discomfort.[789] Ventricular fibrillation or aborted sudden cardiac death occurs more often at night than during the day. The time of onset of drug-induced Brugada syndrome after initiation of therapy with causative agents ranges from weeks to years; only a small proportion of cases occur with drug exposure <72 hours.[795]

For patients with suspected nondrug-induced Brugada syndrome, sodium channel-blocking drugs such as ajmaline, flecainide, pilsicainide, or procainamide may be administered as a component of the diagnostic process to provoke/unmask the type I ECG pattern.[789] Differential diagnosis of drug-induced Brugada syndrome includes exclusion of other arrhythmias (**Table 25-18**). In addition, other conditions that may mimic the Brugada ECG pattern include arrhythmogenic right ventricular cardiomyopathy, right ventricular ischemia or infarction, pulmonary embolism, cardiac tamponade, early repolarization syndrome, hyperkalemia, hypokalemia, hypercalcemia, or hypothermia.[750]

RISK FACTORS

Risk factors for drug-induced Brugada syndrome are presented in **Table 25-19**. As mentioned previously, male sex is a risk factor. In addition, fever is a risk factor/trigger for arrhythmias associated with drug-induced Brugada syndrome.[795] The risk of drug-induced Brugada syndrome appears to be related to drug dose, and many of the reported cases occurred in patients receiving high doses or overdoses of potentially causative age-nts.[759,761,763-765,768,769,772,784] In one analysis, drug toxicity was associated with 46% of 74 cases of Brugada syndrome associated with noncardiac drugs.[795]

Table 25-18 Conditions to Consider in the Differential Diagnosis of Drug-Induced Brugada Syndrome

- Atrial fibrillation
- Atrial flutter
- Atrial tachycardia
- Atrioventricular nodal re-entrant tachycardia
- Idioventricular tachycardia
- Junctional tachycardia
- Non-Brugada syndrome idioventricular tachycardia
- Non-Brugada syndrome monomorphic ventricular tachycardia
- Non-Brugada syndrome ventricular fibrillation
- Sinus tachycardia
- TdP

TdP = torsades de pointes.

Table 25-19 Risk Factors for Drug-Induced Brugada Syndrome

- Fever
- High doses/overdoses of potentially causative agents
- Male sex

MORBIDITY AND MORTALITY

Brugada syndrome is associated with sudden cardiac death. The risk of fatal or near-fatal arrhythmias in patients with Brugada syndrome who had been previously asymptomatic ranges from 1% to 8% over 30–40 months of follow-up.[789] In patients with nondrug-induced Brugada syndrome, the incidence of cardiac events (appropriate implantable cardioverter-defibrillator shocks or sudden cardiac death) was found to be 5% over a mean follow-up period of 32 months (range 14–54 months).[796] The cardiac event rate was highest in those patients who had a previous aborted episode of sudden cardiac death (7.7%) compared with those with a history of syncope (1.9%) or those who remained asymptomatic (0.5%).[796]

The incidence of lethal arrhythmias in patients with drug-induced Brugada syndrome is unknown, but fatal and near-fatal cases have been reported. In a study of 74 cases of Brugada syndrome (manifested by the classic ECG pattern) associated with noncardiac drugs, 23 patients (31%) experienced monomorphic ventricular tachycardia (4/74, 5%) or ventricular fibrillation or pulseless ventricular tachycardia (19/74, 26%).[795] The incidence of mortality was 13%.[795]

PREVENTION

Drugs that are known to provoke or unmask the Brugada syndrome should be avoided in patients with a previous diagnosis of Brugada syndrome. For patients with undiagnosed Brugada syndrome, prevention of drug-induced Brugada syndrome is difficult until the syndrome has been unmasked or provoked by drug therapy.

MANAGEMENT

In patients for whom drugs provoke or unmask Brugada syndrome, the causative agent(s) should be discontinued immediately. Intravenous procainamide should be avoided as a therapy for monomorphic ventricular tachycardia; intravenous amiodarone may be used cautiously. Although it inhibits sodium-channel conductance, amiodarone has not yet been reported to provoke or unmask Brugada syndrome, possibly because of other effects, including inhibition of potassium conductance. Alternatively, the patient can be sedated for performance of direct current cardioversion. Patients who experience ventricular fibrillation should be treated according to Advanced Cardiac Life Support guidelines.[190,191]

INFORMATION FOR PATIENTS

Patients with known Brugada syndrome who require therapy with drugs such as psychotropic agents that may cause ventricular arrhythmias by unmasking or exacerbating the syndrome should be told that the medication may, in rare cases, cause the heart rate (pulse) to become faster. These patients should be instructed to consult their pharmacist or physician if their heart rate increases to above 100–120 bpm or if they feel palpitations, lightheaded, dizzy, tired, weak, short of breath, or chest pain. Patients with known Brugada syndrome should be advised to consume alcohol in moderation, not to the point of intoxication.

CHAPTER 26

Supraventricular Arrhythmias

James E. Tisdale

Drugs may induce a variety of supraventricular arrhythmias that may be associated with symptoms, hemodynamic instability, stroke, and, in some cases, an increased risk of death. Supraventricular arrhythmias that may be induced by drugs include sinus bradycardia, atrioventricular (AV) node block, atrial fibrillation or flutter, atrial tachycardia, and AV nodal re-entrant tachycardia.

SINUS BRADYCARDIA/ATRIOVENTRICULAR BLOCK

Sinus bradycardia is defined as a sinus rate <60 bpm.[1] Drugs that inhibit sinus node function resulting in sinus pauses or sinus arrest are also included in this section. Sinus pauses occur when the function of the sinus node is impaired transiently, leading to "pauses" without P-waves on the electrocardiogram.[1-3] Sinus pauses are also known as periods of sinus arrest.

AV block occurs when conduction of impulses from the atria to the ventricles through the AV node is inhibited.[3] AV block is classified as first, second, or third degree. First-degree AV block is defined as prolongation of the PR interval to >0.2

seconds. Second-degree AV block is a progression of AV nodal dysfunction to the point at which some impulses are not conducted from the atria to the ventricles. Third-degree AV block, often referred to as complete heart block or AV dissociation, is defined by the absence of a relationship between atrial and ventricular depolarization. During third-degree AV block, atrial depolarization and ventricular depolarization occur independently, as a result of the complete inability of the AV node to conduct impulses.[3]

CAUSATIVE AGENTS

Sinus bradycardia with or without sinus pauses may be associated with a wide variety of drugs (**Table 26-1**).[4-522] In addition to occurring as a result of drugs administered orally or intravenously, sinus bradycardia and sinus pauses may be induced by drugs administered as eye drops. Numerous cases of sinus bradycardia associated with topical adrenergic β-receptor antagonists (β-blockers) have been reported.[523,524] The incidence of sinus bradycardia associated with topical timolol is significantly higher (18.4%) than that associated with topical carteolol (4.5%).[523] The lower incidence of sinus bradycardia associated with carteolol may be a result of the intrinsic sympathomimetic activity of the drug. Chronic cocaine use has been shown to increase the odds of bradycardia and severe bradycardia by factors of 3.02 and 5.11, respectively.[103] Drugs that have been reported to cause AV block are listed in **Table 26-2**.[4,5,46,148,154,158,174,176,179,198,199,202,204,207,209,212-214,216,345-347,446,519,525-679]

Table 26-1 Agents Implicated in Drug-Induced Sinus Bradycardia

Drug	Incidence	Level of Evidence[a]
Adenosine[4-6]	1–8%	A
Amiodarone[7-14]	3–20%	A
Amisulpride[15]	NK	C
Baclofen[16-24,b]	NK	C
β-blockers[25-35]	0.6–25%	A
Bupivacaine[36-43]	2–32%	A
Capecitabine[44,45]	NK	C
Carbamazepine[46,47]	NK	C
Cimetidine[48-54]	NK	C

Cisplatin[55-60]	NK	B
Citalopram[61-65]	0.1–2.4%	B
Clonidine[66-99]	5–17.5%	A
Clozapine[100,101]	NK	C
Cocaine[102,103]	23–48%	B
Cytarabine[106-109]	NK	C
Dexamethasone[110-113]	NK	B
Dexmedetomidine[114-144]	4.4–55%	A
Diazepam[50,b]	NK	C
Digoxin[145-151,b]	0–7%	B
Diltiazem[152-165]	4.2–16%	A
Dipyridamole[166-172,c]	0.5–6.7%	B
Disopyramide[173-177]	0–4%	B
Donepezil[177-186]	0.6–48% HR 1.4 (95 % CI 1.1–1.6)	A
Dronedarone[187-190]	0.7–2.3% OR 1.45 (95% CI 1.02–2.08)	A
Dovitinib[191]	5%	B
Escitalopram[192-194]	NK	C
Fingolimod[195-215]	0.5–37%	A
Flecainide[216-223]	2–13.2%	B
Fludarabine[224]	NK	C
5-fluorouracil[225-227]	12%[d]	B
Fluoxetine[228-234]	NK	B
γ-hydroxybutyric acid[235-240]	NK[e]	B
Granisetron[241,242]	NK	A
Halothane[243-246]	11–24%	A
Ibutilide[247-250]	0–4.5%	B
Idarubicin[251]	NK	C
Irinotecan[252,253]	NK	C
Isradipine[254,c]	NK	C
Ivabradine[255-267]	3.7–15.7% OR 6.54 (95% CI 3.3–012.9)	A
Ketamine[268-273]	0–5.5%[f]	B

Lidocaine[95,274-283]	0–9.3%	B
Memantine[184,284]	7%	B
Mepivacaine[285-287]	5–13%	A
Methadone[288-293]	NK	C
Methylprednisolone[111,294-307]	2.5%[g]	B
Milrinone[308]	0–13%	A
Mycophenolate[195,196]	6.4–53%	B
Neostigmine[309-321]	OR 2.7 (95% CI 1.4–5.4)	B
Nicardipine[322-325]	10–12%	A
Nitroglycerin[326-334]	0–0.7%	B
Octreotide[335-339]	NK	C
Olanzapine[340-344]	0.25%–0.7%	B
Paclitaxel[345-353]	3–29%	A
Pentazocine[354]	5%[h]	B
Prednisone[355,356]	NK	C
Pregabalin[97]	7.5%	B
Propafenone[357-362]	0.7%[i] 10%[j]	B B
Propofol[363-384]	0–50% (14.7% in analysis of combined studies)	A
Physostigmine[312,385-387]	NK	B
Pyridostigmine[312,386,388]	NK	C
Ranitidine[389-397]	NK	C
Remifentanil[398-411]	0–39%	A
Risperidone[412-414]	NK	C
Sevoflurane[244,415-428]	0–53%	A
Sotalol[429-452]	1.5–17.2%	A
Succinylcholine[453-465]	0–50%	A
Tacrolimus[466,467]	NK	C
Tetracaine[468-470]	NK	C
Thalidomide[471-484]	3.2–54%	A
Tivantinib[485]	21%	B
	NK	C

Tizanidine[486-489]		
Verapamil[243,490-522]	0–11%	A

CI = confidence interval, HR = hazard ratio, NK = not known, OR = odds ratio.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Predominantly in overdose or with supratherapeutic plasma concentrations.

[c] Reported with intravenous use.

[d] Incidence associated with 5-fluorouracil-based chemotherapy regimens.

[e] Incidence in γ-hydroxybutyric acid intoxication: 6–38%.[236,239]

[f] Incidence as high as 21.1% in infants.[270]

[g] Incidence as high as 42% following pulse doses of 1,000 mg.[299]

[h] Intramuscular administration in children.

[i] Oral propafenone.

[j] Intravenous propafenone.

EPIDEMIOLOGY

The overall incidence of drug-induced sinus bradycardia or AV block is unknown. The incidence of sinus bradycardia and sinus pauses associated with specific agents, where known, is presented in Table 26-1, and the incidence of drug-induced AV block associated with specific drugs, where known, is presented in Table 26-2.

Amiodarone has been reported to cause sinus-node and AV nodal bradyarrhythmias requiring pacemaker insertion.[9] In a study of 15,824 patients with atrial fibrillation and a history of myocardial infarction who were receiving amiodarone, the incidence of pacemaker implantation was 2.2% per person-year (mean duration [±SD] of follow-up, 1.8 ± 1.5 years), and was 5.2% per person-year during the first 90 days of therapy.[9] The odds ratio for pacemaker insertion to treat bradyarrhythmias associated with amiodarone use was 2.14 (95% CI 1.30–3.54).[680] Although the incidence of sinus bradycardia associated with conventional doses of intravenous amiodarone (1–2 g/24 hr) is similar to that associated with oral amiodarone,[681] the incidence may be as high as 10% when doses of 3 g per 24 hours are administered.[682]

Sinus bradycardia or arrest or AV block may be caused by digoxin, primarily in overdose or other situations in which serum digoxin concentrations become elevated.[148] The overall incidence of sinus bradycardia or AV block associated with digoxin is unknown. In an analysis of patients with a discharge diagnosis of digoxin intoxication, “definite” sinus bradycardia and sinus pauses <2 seconds were documented in 26% and 19%, respectively, of those with digoxin intoxication.[148] In addition, "definite" second- or third-degree AV block was documented in 33% of patients with digoxin intoxication.[148] Sotalol has been reported to cause clinically important sinus bradycardia and sinus pauses in up to 17.2% of patients treated for atrial fibrillation, with 2.5% requiring permanent pacemaker implantation.[445]

Ivabradine is a recent addition to therapy for patients with heart failure with reduced ejection fraction (HFrEF) and is indicated for patients with HFrEF with heart rates >70 bpm who are on maximally tolerated doses of β-blockers or are intolerant of β-blocker therapy. Ivabradine is associated with sinus bradycardia in up to 16% of patients. A meta-analysis of placebo-controlled studies of ivabradine in patients with stable coronary artery disease with and without HFrEF reported an odds ratio for bradycardia of 6.54 (95% CI 3.30–12.9, p <0.01).[264] Fingolimod, which is indicated for relapsing forms of multiple sclerosis, is associated with sinus bradycardia in up to 37% of patients.[195]

Zeltser et al.[568] reviewed a series of 169 consecutive patients admitted or discharged with the diagnosis of second- or third-degree AV block that was not caused by acute myocardial infarction, vasovagal syncope, radiofrequency ablation, or digitalis toxicity. Of these, 54% were receiving therapy with β-blockers with or without diltiazem, diltiazem alone, or verapamil. The investigators reported that drug discontinuation was followed by resolution of AV block in 41% of patients but that 56% of these patients subsequently had recurrence of AV block in the absence of causative drugs. Based on their criteria for causation, the investigators concluded that drugs were the specific cause of AV block in only 15% of the patients who were receiving therapy with β-blockers with or without diltiazem, diltiazem alone, or verapamil.[568]

MECHANISMS

Drug-induced sinus bradycardia may be caused by inhibition of automaticity of the node, slowing of sinus node conduction, or prolongation of sinus node repolarization (**Table 26-3**). AV block may be caused by agents that inhibit AV node conduction or prolong AV node repolarization (**Table 26-4**). Both the sinus node and the AV node are heavily influenced by sympathetic and parasympathetic nervous system activity. Drugs that inhibit activity of the sympathetic nervous system (e.g., β-blockers) and drugs that stimulate the parasympathetic nervous system (e.g., neostigmine, physostigmine, pyridostigmine) may cause sinus bradycardia or AV block. The action potentials of both the sinus node and the AV node depend primarily on calcium and sodium flux, and calcium or sodium channel inhibitors may cause sinus bradycardia, AV block, or both.

Table 26-2 Agents Implicated in Drug-Induced Atrioventricular Block

Drug	Incidence	Level of Evidence[a]
Aconite[525,526]	NK	C
Adenosine[4,5,527-551]	3–15% RR 7.88 (95% CI 4.15–14.9) RR 6.78 (95% CI 2.15–21.38)	A
Amiodarone[552-559]	0–14.8%	A
Amitriptyline[560,561]	NK	C

[a]Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials;

Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

Nitrates may cause a syndrome associated with sinus bradycardia and hypotension.[326-334] Sinus bradycardia induced by nitrates is an idiosyncratic reaction. This syndrome resembles neurocardiogenic syncope but may occur when patients are in the supine position. The mechanism of nitrate-induced sinus bradycardia remains unclear, but evidence suggests that nitrates may stimulate peripheral sensory receptors with vagal afferents to the medulla, resulting in sympathetic nervous system inhibition via stimulation of central α_2-receptors (Table 26-3).[683]

Table 26-3 Mechanisms of Drug-Induced Sinus Bradycardia

Drug	Mechanism
All drugs that may cause sinus bradycardia (except nitrates)	Inhibition of automaticity of the sinus node and/or slowing of sinus node conduction and/or prolongation of sinus node repolarization
β-blockers	Inhibit activity of sympathetic nervous system, leading to inhibition of automaticity of sinus node
Clonidine	Stimulates central α_2-receptors, reducing release of norepinephrine
Fingolimod	Modulation of the sphingosine 1-phosphate (S1P) receptors

Ivabradine	Inhibition of hyperpolarization-activated cyclic nucleotide-gated “funny” (I_f) channels in the sinus node
Neostigmine, physostigmine, pyridostigmine	Stimulate activity of the parasympathetic nervous system, leading to inhibition of automaticity of sinus node
Nitroglycerin	Stimulates peripheral sensory receptors with vagal afferents to the medulla, resulting in sympathetic nervous system inhibition via stimulation of central α_2-receptors

Table 26-4 Mechanisms of Drug-Induced Atrioventricular Block

Drug	Mechanism
All drugs that may cause AV block	Inhibition of AV node conduction
β-blockers	Inhibit activity of sympathetic nervous system, leading to inhibition of conduction through the AV node
Clonidine	Stimulates central α_2-receptors, reducing release of norepinephrine
Fingolimod	Modulation of the sphingosine 1-phosphate (S1P) receptors
Neostigmine, physostigmine, pyridostigmine	Stimulate activity of the parasympathetic nervous system, leading to inhibition of conduction through the AV node

AV = atrioventricular.

Ivabradine is a hyperpolarization-activated cyclic nucleotide-gated “funny” channel (I_f) blocker, the primary mechanism of which is to slow heart rate in patients with HFrEF.[259,260] Sinus bradycardia is an extension of the pharmacologic effect of the drug. Fingolimod causes sinus bradycardia via modulation of the sphingosine 1-phosphate (S1P) receptors.[684] S1P contributes to regulation of heart rate and cardiac conduction via modulation of intramyocyte calcium concentrations.[685]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Normal heart rate is usually defined somewhat arbitrarily as ranging between 60 and 100 bpm. However, many individuals routinely have heart rates <60 bpm and even <50 bpm without evidence of symptoms. Patients with symptomatic sinus bradycardia resulting in the need for medical attention typically have heart rates between 30 and 50 bpm, resulting in hemodynamic compromise. Signs and symptoms associated with clinically important sinus bradycardia and sinus pauses are listed in **Table 26-5**.[1,3]

Table 26-5 Signs and Symptoms Associated with Drug-Induced Sinus Bradycardia and Atrioventricular Block

- Dizziness
- Light-headedness
- Fatigue
- Lethargy
- Dyspnea
- Weakness
- Presyncope
- Syncope
- Chest pain
- Symptoms of heart failure

First-degree AV block is a common electrocardiographic phenomenon that is almost always asymptomatic and is, therefore, not a drug-induced disease as defined in this text.[3] However, if extreme prolongation of the PR interval occurs (>0.3 sec), patients may experience symptoms during exercise due to AV dysynchrony, as the PR interval may not shorten enough as the RR interval decreases.[3] Second- and third-degree AV block can result in bradycardia, leading to symptoms that result in the need for medical attention or even requiring hospitalization.

Second-degree AV block occurs most commonly in two distinct patterns. Mobitz type I second-degree AV block (also known as Wenckebach) is characterized by progressive prolongation of the PR interval on the electrocardiogram (ECG) until a P-wave is not followed by a QRS complex.[3] Mobitz type I is usually caused by impulse conduction delay in the AV node (as opposed to further down in the bundle of His).[1] Mobitz type II second-degree AV block is typified by constant PR intervals with abrupt, intermittent absence of QRS complexes. Mobitz type II second-degree AV block often occurs in specific patterns with P-wave to QRS complex ratios such as 2:1 or 3:1. This type of second-degree AV block is likely caused by impulse-conduction delay in the bundle of His.

During third-degree AV block, the AV node is completely unable to conduct impulses, and atrial depolarization occurs independently of ventricular depolarization. Therefore, P-waves and QRS complexes are present on ECG but are unrelated to one another. Third-degree AV block can occur either in the AV node itself or further down in the bundle of His.[3]

Second- or third-degree AV block may result in bradycardia, with heart rates in the range of 40–60 bpm, and sometimes as low as 20–40 bpm. Symptoms of second- or third-degree AV block are the same as those associated with sinus bradycardia (Table 26-5).

Drug-induced sinus bradycardia or AV block must be distinguished from other causes of sinus or AV node impairment. Dysfunction of the sinus node unrelated to drug therapy is common, with a prevalence as high as 1 in 600 patients over the age of 65 years.[686] Intrinsic AV nodal abnormalities also may occur during the aging process. Transient sinus node dysfunction may occur in the setting of acute myocardial ischemia or infarction when the infarct/ischemia-related vessel is the right coronary artery or the left circumflex artery, but permanent sinus-node damage in this setting is uncommon. Myocardial infarction may result in some degree of permanent AV nodal dysfunction in some patients. Conditions to consider in the differential diagnosis of drug-induced sinus bradycardia or AV block are listed in **Table 26-6**.[1]

Drug-induced sinus or AV node dysfunction can often be distinguished from nondrug-related sinus bradycardia or AV block. When a patient with symptoms that appear to be related to sinus bradycardia/sinus pauses/sinus arrest or AV block seeks medical attention, therapy with drugs known to induce sinus or AV node dysfunction should be discontinued. If the sinus or AV node dysfunction persists after five half-lives of the respective drug(s) have passed, a drug-induced cause may be ruled out. While awaiting drug washout, evaluation and diagnostic testing for nonpharmacologic causes can be performed, including determination of serum potassium and magnesium concentrations, thyroid function tests, and assessment for myocardial ischemia or infarction. However, it may not be possible or desirable in every case to discontinue therapy with drugs suspected of causing sinus bradycardia or AV block. For example, β-blocker therapy should not generally be discontinued in a patient treated for HFrEF or after myocardial infarction. Rather, therapy with the β-blocker should be continued and implantation of a permanent pacemaker considered as a means to protect against possible drug-induced sinus or AV node dysfunction.

Table 26-6 Conditions to Consider in the Differential Diagnosis of Drug-Induced Sinus Bradycardia or Atrioventricular Block[a]

- Age-related idiopathic degenerative fibrosis of the sinus or AV node
- Myocardial ischemia/infarction (results in transient, not permanent, sinus bradycardia or AV block)
- Hypothyroidism
- Hypoxia
- Hypothermia
- Electrolyte abnormalities (hyperkalemia, hypokalemia, hypermagnesemia)
- Congenital heart disease
- Amyloidosis

- Hemochromatosis
- Sarcoidosis
- Myocarditis
- Systemic lupus erythematosus
- Scleroderma
- Rheumatoid arthritis
- Myotonic muscular dystrophy
- Surgical trauma (valve replacement, heart transplantation, correction of congenital heart disease)
- Chagas disease
- Endocarditis
- Diptheria
- Neurocardiac syncope
- Carotid sinus hypersensitivity
- Coughing
- Micturition
- Defecation
- Vomiting

AV = atrioventricular.
[a]See reference 1 for more information.

RISK FACTORS

Risk factors for drug-induced sinus bradycardia are listed in **Table 26-7**. Higher drug doses may increase the risk for sinus bradycardia.[9] Conditions that may result in elevated plasma concentrations of drugs known to cause sinus bradycardia increase the risk. Patients with kidney disease who are receiving renally eliminated drugs that may cause sinus bradycardia (atenolol, clonidine, digoxin) are also at increased risk. Age >65 years is a risk factor for citalopram-induced bradycardia; the incidence was 2.4% in patients >65 years of age compared to 0.2% in patients younger than 65 years (p <0.05).[64] Kidney disease has been identified as a risk factor for sinus bradycardia associated with clonidine.[75] Drugs that have been reported to cause sinus bradycardia or AV block that require dose adjustment in patients with kidney disease are listed in **Table 26-8**, and drugs that have been reported to cause sinus bradycardia or AV block that require dose adjustment in patients with liver disease are listed in **Table 26-9**. In addition, concomitant use of drugs that inhibit the hepatic metabolism of drugs known to induce sinus bradycardia should be avoided (**Table 26-10**).[688]

Table 26-7 Risk Factors for Drug-Induced Sinus Bradycardia or Atrioventricular Block

Sinus bradycardia[9,53,63,242,420,421,423,681-687]

- Pretreatment heart rate <60 bpm
- Underlying sinus-node dysfunction (may occur with advancing age)

- Impaired baroreflex control (risk factor for nitroglycerin-induced sinus bradycardia)
- Concomitant use of less than one sinus-node inhibiting drug
- Elevate plasma drug concentrations due to kidney or liver disease or drug interactions
- Age >65 years (citalopram-induced bradycardia)
- Amiodarone dose >200 mg daily
- Female (risk factor for pacemaker implantation due to amiodarone-induced bradycardia)
- Down syndrome (risk factor for sevoflurane-induced bradycardia)

Atrioventricular block[546,554,688]

- Concomitant use of less than one AV-blocking drug
- Pretreatment PR interval >0.2 sec
- Underlying AV nodal disease (may occur with advancing age)
- Elevated plasma drug concentration due to kidney or liver disease or drug interactions
- Hypothyroidism (may be a risk factor for amiodarone-induced AV block)
- Prior use of aspirin (adenosine-induced AV block)

AV = atrioventricular, bpm = beats per minute.

Table 26-8 Drugs Known to Cause Sinus Bradycardia or Atrioventricular Block That May Require Dose Adjustment or Are Contraindicated in Patients with Kidney Disease

- Acebutolol
- Amisulpride
- Atenolol
- Baclofen
- Betaxolol
- Capecitabine
- Carteolol
- Cimetidine
- Cisplatin (recommended to be avoided in patients with pre-existing kidney disease)
- Clonidine
- Dexmedetomidine
- Digoxin
- Disopyramide
- Famotidine
- Flecainide
- Fludarabine
- Guanabenz
- Idarubicin
- Isradipine
- Memantine
- Milrinone
- Mycophenolate
- Nadolol
- Nicardipine
- Ranitidine
- Risperidone
- Sotalol
- Tacrolimus

Table 26-9 Drugs Known to Cause Sinus Bradycardia or Atrioventricular Block That May Require Dose Adjustment or Are Contraindicated in Patients with Liver Disease

- Acebutolol
- Citalopram
- Dronedarone
- Escitalopram
- Fluoxetine
- Idarubicin
- Ivabradine
- Paclitaxel
- Propafenone
- Risperidone
- Tacrolimus

Other interactions may result in sinus bradycardia. Dipyridamole inhibits the cellular uptake of adenosine; therefore, patients receiving adenosine concomitantly with dipyridamole are at increased risk of adenosine-associated sinus bradycardia/sinus pauses.[6,689] A number of drugs inhibit the elimination of digoxin, particularly amiodarone, verapamil, and quinidine, and concomitant use of these drugs with digoxin increases the risk of digoxin-induced sinus bradycardia, unless appropriate digoxin dose reduction is implemented.[690-692] In addition, patients receiving therapy with more than one drug known to reduce heart rate are at increased risk.[75,309]

Women are at greater risk for amiodarone-induced bradycardia requiring implantation of a permanent pacemaker.[693] In a study of 1,005 patients with new-onset atrial fibrillation, the hazard ratio for amiodarone use requiring a permanent pacemaker was 4.69 (95% CI 1.99–11.05) in women, as compared with 1.05 (95% CI 0.42–2.58) in men.[693] Mechanisms for the increased risk of bradycardia requiring pacemaker implantation in women are unknown.

Down syndrome has been reported to be a risk factor for bradycardia induced by sevoflurane.[425,426,428] The mechanism of increased risk is unknown, but individuals with trisomy 21 exhibit a decreased heart rate response to orthostatic challenges, suggesting that these patients may have blunted activation of the sympathetic nervous system or impaired parasympathetic regulation of heart rate.[428]

Specific risk factors for the majority of drug-induced AV block have not been identified. In the study by Zeltser et al.[568] of 169 consecutive cases of AV block, there were no significant differences in age, male sex, or presence of hypertension or ischemic heart disease between patients receiving therapy with β-blockers with or without diltiazem or verapamil and those not receiving therapy with drugs that could induce AV block. In a retrospective analysis of 102 cardiac transplant patients who received adenosine for stress myocardial perfusion imaging, prior use of aspirin and baseline first-degree AV block were independent risk factors for adenosine-induced second- or third-degree AV block.[546] Possible risk factors for drug-induced AV block are listed in Table 26-7. Risk factors have been identified for AV block induced by digoxin and include the drug interactions listed above, hypokalemia, hypomagnesemia, hypoxia, hypothyroidism, and inadequate dose reduction in patients with kidney disease.[694]

Table 26-10 Drugs Known to Cause Sinus Bradycardia or Atrioventricular Block That Are Substrates for Enzymes of the Cytochrome P-450 System[688]

1A2	2B6	2C8	2C9	2C19	2D6	2E1	3A4,5,7
Amitriptyline	Ketamine	Paclitaxel	Amitriptyline	Amitriptyline	Amitriptyline	Halothane	Carbamazepine
Clozapine	Methadone		Fluoxetine		Carvedilol	Sevoflurane	Cocaine
Olanzapine	Propofol				Clonidine		Diazepam
Propranolol					Flecainide		Diltiazem
Tizanidine					Fluoxetine		Lidocaine
Verapamil					Imipramine		Methadone
					Lidocaine		Paclitaxel
					Metoprolol		Propranolol
					Nebivolol		Quinidine
					Propafenone		Risperidone
					Propranolol		Tacrolimus
					Risperidone		Verapamil
					Timolol		

MORBIDITY AND MORTALITY

The incidence of morbidity, hospitalization, or death associated with drug-induced sinus bradycardia or AV block is unknown. Drug-induced sinus bradycardia or AV block may result in the need for temporary or permanent pacemaker implantation.[9,62,662,680] In a population of patients with new-onset atrial fibrillation, the adjusted hazard ratio for amiodarone use leading to a requirement for a permanent pacemaker was 2.01 (95% CI 1.08–3.76).[693] Death due to drug-induced sinus bradycardia or AV block is likely very uncommon.

PREVENTION

Drug-induced sinus or AV node dysfunction (or both) is often preventable (**Table 26-11**). When possible, drugs with the potential to inhibit sinus or AV node function should be avoided in patients with known sinus or AV node dysfunction in the absence of a functioning pacemaker. Once a pacemaker has been implanted, however, patients with sinus node dysfunction may receive sinus node-inhibiting drugs, and patients with AV node dysfunction may receive AV node-inhibiting agents. Patients who are taking drugs with the potential to cause sinus bradycardia, sinus pauses, or AV block should be taught to monitor their heart rate daily and to consult their pharmacist or physician if heart rate falls below 50 bpm or if they experience symptoms of bradycardia (Table 26-5). Combinations of drugs that may inhibit sinus or AV node function should be minimized but are not contraindicated if the benefits of such therapy outweigh the risks.

Drug-induced sinus or AV node dysfunction may be prevented by not exceeding maximum daily doses of drugs known to cause these drug-induced diseases and by appropriate dose adjustment of specific drugs to account for organ dysfunction, drug interactions, or both. Maintaining serum digoxin concentrations <2 ng/mL, and optimally <1 ng/mL, reduces the risk of digoxin-associated sinus or AV node dysfunction. In certain circumstances, substituting medications within a class may prevent drug-induced sinus or AV node dysfunction. For example, a patient with kidney disease who is receiving atenolol is at higher risk for atenolol-induced sinus bradycardia or AV block as a result of diminished atenolol clearance. In this situation, replacing atenolol with a nonrenally cleared β-blocker such as metoprolol or propanolol may reduce the likelihood of drug-induced sinus bradycardia or AV block.

Table 26-11 Approaches to Help Prevent Drug-Induced Sinus Bradycardia and Atrioventricular Block

For all drugs that may cause sinus bradycardia, AV block, or both

- Patient should take pulse daily, report if <50 bpm
- Do not exceed maximum daily doses
- Use combinations of drugs that may cause sinus bradycardia or AV block only when necessary and when the benefits likely outweigh the risks
- Appropriately adjust drug doses for liver or kidney disease
- Avoid sinus or AV node-inhibiting drugs in patients with underlying sinus node dysfunction, unless a functioning pacemaker is present (in the case of AV node-inhibiting drugs, there must be a functioning ventricular pacemaker)

For digoxin

- *Measure serum digoxin concentrations:*
  - If kidney function is changing
  - If a drug that interacts with digoxin is added to therapy
  - Every 6 months if there is no kidney disease or concomitant use of interacting drugs

AV = atrioventricular.

Patients receiving drugs known to inhibit AV node conduction should undergo a 12-lead ECG periodically and at least every 6 months. First-degree AV block is not an absolute contraindication to receiving AV node-blocking drugs, but the PR interval should be monitored every 3–6 months to ensure that AV block is not progressing. In addition, combinations of AV node-blocking drugs are best avoided in patients with pretreatment PR intervals >0.2 seconds. If the PR interval progresses to >0.2 seconds while on AV node-blocking therapy, it is not necessary to discontinue therapy, but more frequent ECG monitoring is recommended and administration of additional AV node-blocking agents should be avoided.

Table 26-12 Management of Drug-Induced Sinus Bradycardia or Atrioventricular Block

- Discontinue the causative agent
- Temporary pacemaker
- *If underlying sinus or AV node dysfunction:* Permanent pacemaker may be necessary (if AV node dysfunction, must be a ventricular pacemaker)
- *In severe cases:* Atropine 0.5–1 mg q 3–5 min until heart rate increases or total dose of 1.5–3 mg is administered
- *If atropine not effective:* Epinephrine 2–10 mcg/min or dopamine 2–10 mcg/kg/min continuous IV infusion
- *If due to calcium-channel blocker or β-blocker overdose:*
  - Gastric lavage (within 1 hour of ingestion)
  - Activated charcoal 25–50 g in an aqueous slurry of 120–240 mL water (within 1 hour of ingestion)
  - Glucagon 3–10 mg (0.05–0.15 mg/kg) intravenously followed by continuous infusion of 3–5 mg/hr (β-blocker overdose only)
  - Calcium 0.3 mEq/kg intravenously, administered as calcium gluconate (10%) 0.6 mL/kg or calcium chloride (10%) 0.2 mL/kg over 5–10 minutes, followed by 0.3 mEq/kg/hr
  - *HIE:* Regular insulin 1 international unit/kg bolus followed by continuous IV infusion of 0.5–1 international unit/kg/hr
- Temporary pacemaker, if necessary

AV = atrioventricular, HIE = hyperinsulinemia/euglycemia therapy, IV = intravenous.

MANAGEMENT

Management options for patients with drug-induced sinus bradycardia or AV block are presented in **Table 26-12**. In some cases, a reduction in dose of the offending medication may be sufficient, but in most cases in which drug-induced sinus or AV node dysfunction has resulted in a hospitalization, discontinuation of therapy is necessary. In the case of sinus bradycardia or AV block induced by adenosine, treatment is not usually required because the drug is metabolized very quickly (half-life = 10 seconds) and the heart rate usually returns to pretreatment values within 20–30 seconds.

Percutaneous insertion of a temporary pacemaker may be necessary. If the patient is subsequently diagnosed with underlying intrinsic sinus or AV node dysfunction, therapy with the offending medication may be reinitiated after the implantation of a permanent pacemaker. In severe cases, intravenous atropine may be administered in doses of 0.5–1 mg every 3–5 minutes to a total dose of 1.5–3 mg, the dose at which full blockade of the parasympathetic nervous system occurs in humans.[695,696] If atropine is not effective, then epinephrine (2–10 mcg/min) or dopamine (2–10 mcg/kg/min) may be administered. Transcutaneous pacing may be necessary for patients in whom pharmacotherapy is ineffective.

If the drug-induced bradycardia or AV block is a result of an overdose of verapamil, diltiazem, or a β-blocker, gastric lavage may be performed if the patient presents within 1 hour of ingestion. Activated charcoal may be administered and may be particularly useful if the drug was ingested in the form of a sustained-release preparation. For management of sinus bradycardia/AV block due to a β-blocker overdose, treatment with intravenous glucagon, calcium, and/or hyperinsulinemia-euglycemia (HIE) therapy may be initiated.[697,698] Glucagon may be administered as an intravenous bolus dose of 3–10 mg (0.05–0.15 mg/kg), followed by a continuous infusion of 3–5 mg/hr (0.05–0.10 mg/kg/hr), titrated to achieve an adequate hemodynamic response.[698] Calcium 0.3 mEq/kg may be administered, either as calcium gluconate (10%) 0.6 mL/kg or calcium chloride (10%) 0.2 mL/kg over 5–10 minutes, followed by an infusion of 0.3 mEq/kg/hr.[697] Although recommended, evidence supporting calcium infusion for β-blocker overdose is somewhat limited.[697] For patients with β-blocker overdose and sinus bradycardia/AV block refractory to other treatments, HIE may be administered as regular insulin 1 international unit/kg bolus followed by continuous infusion of 0.5–1 international unit/kg/hr. The infusion dose may be titrated every 30 minutes to achieve the desired response. Because of the potential for insulin-associated electrolyte shifts, close monitoring of serum electrolyte concentrations during HIE therapy is recommended. Intravenous dextrose 25 g may be administered with the initial insulin bolus to maintain euglycemia (blood glucose 100–250 mg/dL), followed by continuous dextrose infusion at 0.5 g/kg/hr.[697,698]

In refractory cases of β-blocker or calcium-channel blocker overdose, lipid emulsion infusions have been administered with some success.[697,699,700] The mechanism by which lipid emulsion infusions may be effective has not been elucidated completely. Lipid emulsions may act as a lipid sink, pulling lipophilic drugs away from tissue receptors into plasma, where the drug can then be bound to the emulsion.[699] Another theory suggests that lipid emulsions may enhance myocardial availability of free fatty acids, reversing the conversion from lipid to glucose metabolism that occurs in damaged heart muscle, thereby augmenting availability of substrate with which to resume normal metabolism.[699]

If sinus bradycardia/AV block is a result of a presumed or documented overdose of diltiazem or verapamil, evidence supporting the efficacy of specific antidotes is lacking.[697] Several case reports describe administration of HIE for management of calcium-channel blocker overdose and suggest that HIE, at doses described previously, is a reasonable therapeutic option.[697] More limited evidence, also from case reports, is available to support calcium administration for management of calcium-channel blocker overdose; calcium administration may be considered for patients with calcium-channel blocker overdose and shock that are refractory to other treatments.[697] Evidence is insufficient to recommend glucagon for management of calcium channel overdose.[697] In cases of β-blocker or calcium-channel blocker overdose, insertion of a temporary pacemaker may be necessary.

For patients with a history of myocardial infarction or heart failure in whom sinus bradycardia or AV block induced by β-blockers develops, implantation of a permanent pacemaker may be necessary to allow the patient to continue therapy with these agents, which have been shown to prolong survival in these specific conditions.[701-703]

INFORMATION FOR PATIENTS

Patients should be instructed that specific drug(s) may cause the heart rate (pulse) to become slower. Patients should be taught to take their pulse and to monitor their heart rate daily. Patients should be instructed to consult their pharmacist or physician if their heart rate falls below 50 bpm, or if they feel lightheaded, dizzy, tired, weak, short of breath, experience chest pain, or lose consciousness.

ATRIAL FIBRILLATION/ATRIAL FLUTTER

Atrial fibrillation is a supraventricular arrhythmia that is characterized on ECG by an irregularly irregular pattern of narrow QRS complexes, an absence of discernible P-waves and an undulating baseline. Atrial flutter is a supraventricular arrhythmia that is characterized on ECG by a regular pattern of narrow QRS complexes, with discernible P-waves that exhibit a “sawtooth” appearance. Atrial flutter is often associated with a ratio of P-waves to QRS complexes of 4:1, 3:1, or, in some cases, 2:1.

CAUSATIVE AGENTS

Drugs that have been associated with atrial fibrillation or atrial flutter are listed in **Table 26-13**.[229,260,263,264,267,302,308,351,386,541,635,704-834] The majority of drugs that have been associated with induction of atrial fibrillation or flutter are cardiovascular agents, but drugs from other classes have been implicated as well, including alcohol, bisphosphonates, corticosteroids, and anticancer agents.[302,351,725-753,784,786,787,792-794,799-805,812,816,833-844]

EPIDEMIOLOGY

The overall incidence of drug-induced atrial fibrillation or flutter is not known, but it is likely very low. Adenosine has been reported to cause a substantial incidence of atrial fibrillation in patients undergoing treatment for AV nodal re-entrant tachycardia.[711] Although the incidence of alcohol-induced atrial fibrillation (often referred to as the "holiday heart syndrome") is unknown, in a case-control study of patients with acute idiopathic atrial fibrillation, 62% of cases were associated with heavy alcohol use.[728] In a prospective cohort study of the association between self-reported alcohol use and incident atrial fibrillation, moderate alcohol intake was not associated with new-onset atrial fibrillation. However, consumption of 35 or more drinks per week was associated with a hazard ratio for atrial fibrillation of 1.45 (95% CI 1.02–2.04) in men.[734] About 5% of cases of atrial fibrillation in men were estimated to be attributable to heavy alcohol intake. In women, consumption of two or more drinks daily was associated with an increased risk of atrial fibrillation (HR 1.60, 95% CI 1.13–2.25) in a prospective study.[735] In a large prospective study of 79,019 men and women, the risk of atrial fibrillation was increased in those who drank 15–21 drinks per week (RR 1.14 [1.01–1.28]) and >21 drinks per week (1.39 [1.22–1.58]) compared to those who drank <1 drink weekly.[746] Even comparatively small amounts of alcohol ingestion appear to increase atrial fibrillation risk; every 10 g of alcohol per day (just under 1 drink daily) is associated with a 5% higher risk of developing new-onset atrial fibrillation.[748] In an epidemiological study of hospital-based healthcare encounters conducted in Texas, residents of counties in which alcohol sales were not restricted had a significantly greater prevalence of atrial fibrillation than residents of "dry" counties, where alcohol sales were prohibited, and conversion of counties from "dry" to unrestricted alcohol sales resulted in significant increases in atrial fibrillation prevalence.[749]

In a randomized study of the prevention of fractures in postmenopausal women, the bisphosphonate drug alendronate was found to increase the risk of "serious" atrial fibrillation (1.5% versus 1% in the placebo group, relative hazard 1.51, 95% CI 0.97–2.40, $p = 0.07$).[750] However, alendronate did not increase the risk of "all atrial fibrillation adverse events." In addition, in a case-control study in women, a higher proportion of patients with atrial fibrillation had used alendronate as compared with those who had never used any bisphosphonate (odds ratio of atrial fibrillation 1.86, 95% CI 1.09–3.15).[751] Furthermore, another bisphosphonate drug, zoledronic acid, was reported to increase the risk of "serious" atrial fibrillation as compared with placebo (1.3% versus 0.5%, $p < 0.001$).[833] However, zoledronic acid did not increase the risk of all atrial fibrillation events. In 2008, the FDA released a statement regarding the cardiovascular safety of bisphosphonate drugs in which they stated there was "no clear association between overall bisphosphonate use and the rate of serious or nonserious atrial fibrillation in patients taking bisphosphonates."[845] Since that time, numerous cohort studies have been published indicating a significant association between bisphosphonate use and risk of new-onset atrial fibrillation.[752,835-837,843] In addition, several meta-analyses have reported that bisphosphonate drugs increase the risk of new-onset atrial fibrillation.[839-842,844] In contrast, however, numerous studies published since the FDA’s 2008 statement have not found an association between bisphosphonate use and new-onset atrial fibrillation, and some meta-analyses have not reported an association between bisphosphonate drugs and new-onset atrial fibrillation.[846-852] In view of these discordant studies, the issue as to whether bisphosphonate drugs induced atrial fibrillation remains unresolved.

Table 26-13 Agents Implicated in Drug-Induced Atrial Fibrillation or Atrial Flutter

Drug	Incidence	Level of Evidence[a]
Adenosine[541,704-720]	1–12%[b]	B
Albuterol[721-724]	NK	C
Alcohol[725-749]	OR/RR 1.51 (95% CI 1.3–17.4)[740] HR 1.60 (95% CI 1.02–2.51)[741] HR 1.14 (95% CI 1.04–1.26)[743] HR 1.29 (95% CI 1.02–1.62)[743,c]	B
Alendronate[750-753]	0.5% OR 1.86 (95% CI 1.09–3.15)[751] IR 1.58 (95% CI 1.07–2.33)[752,d] OR 1.97 (95% CI 1.59–2.43)[753]	A
Amiodarone[754-757]	NK	B
Caffeine[724,758-765]	NK	B
1,3 Dimethylamylamine[761]	NK	C
Diltiazem[766]	NK	C
Dobutamine[308,767-783]	0–18%	A
Docetaxel[784]	NK	C
Dopamine[779,785,e]	NK	B
Doxorubicin[786,787]	5.8–13.8%	B
Enoximone[778]	8.3%	A
Fingolimod[635,788]	0.5%	B
Flecainide[789,790]	NK	C
Fluoxetine[229,791]	NK	C
Interleukin-2[792-794]	3.5–4.7%	B

Ipratropium bromide[795]	NK	C
Ivabradine[260,263,264,267, 796,797]	1.3% OR 1.35 (95% CI 1.19–1.53)[264] RR 1.15 (95% CI 1.07–1.24)[796] RR 1.24 (95% CI 1.08–1.42)[797]	A
Levosimendan[781]	0–9.1%	A
Loxapine[791]	NK	C
Metaproterenol[798]	2.5%	A
Methylprednisolone[302,799-805]	1.8%	B
Milrinone[308,806-811]	2.9–5%	A
Mitoxantrone[812]	1.4%	B
Morphine[813]	HR 4.37 (95% CI 3.56–5.36)	B
Ondansetron[814,815]	NK	C
Paclitaxel[351,816]	2% (atrial flutter) 1–1.7% (atrial fibrillation)	B
Physostigmine[386,817]	NK	C
Propafenone[754,790,818]	9%[f]	C
Sildenafil[819-821]	NK	C
Theophylline[721,822-827]	NK	B
Ticagrelor[828]	NK	C
Tiotropium[829]	1.7/100 person-years	B
Vardenafil[830]	NK	C
Verapamil[831,832]	5%	C
Zoledronic acid[833,834]	0.8–2.2%	A

CI = confidence interval, HR = hazard ratio, IR = incidence ratio, NK = not known, OR = odds ratio, RR = relative risk.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Atrial fibrillation, 1–11%, atrial flutter, 1%.

[c] Binge drinkers.

[d] During the first 4–8 weeks of therapy.

[e] Reported following cardiac surgery only.

[f] Percent of patients with atrial fibrillation who develop new atrial flutter during propafenone therapy.[818]

New-onset atrial flutter associated with drugs is also uncommon but has been reported to occur in patients with atrial fibrillation who are receiving Vaughan Williams class IC antiarrhythmic agents (flecainide or propafenone) or amiodarone (Table 26-13).

MECHANISMS

Mechanisms by which some drugs induce atrial fibrillation or flutter are presented in **Table 26-14**. In general, atrial fibrillation is believed to be induced by ectopic impulses originating from pulmonary veins, atria, or both and sustained via multiple atrial re-entrant wavelets.[853] Evidence indicates that the shorter the wavelength, the more likely that atrial fibrillation develops and is sustained.[854,855] Wavelength is the product of the atrial conduction velocity and the atrial effective refractory period.[854,855] Atrial flutter is generally a macro re-entrant atrial tachycardia due to a single re-entrant circuit involving the atrial septum, the lateral atrial wall, and the cavotricuspid isthmus between the annulus of the tricuspid valve and the inferior vena cava.[853]

Table 26-14 Mechanisms of Drug-Induced Atrial Fibrillation/Flutter

Drug	Mechanism
Adenosine	Promotes pulmonary vein ectopic activity Shortens atrial effective refractory period/atrial wavelength
Alcohol	Sympathetic nervous system stimulation Shortens atrial effective refractory period Increases interatrial electromechanical delays Vagal activity
Amiodarone	Some cases likely due to thyrotoxicosis
Dobutamine	Enhances intracellular cAMP, resulting in increased myocyte cytosolic calcium, promoting depolarizations in pulmonary veins Shortens atrial effective refractory periods
Theophylline	Increases atrial automaticity
Other drugs	Unknown

cAMP = 3′–5′cyclic adenosine monophosphate.

Adenosine has been shown to induce atrial fibrillation via a direct stimulatory effect on pulmonary vein tissue, increasing pulmonary vein ectopic activity.[856] Adenosine has been also shown to shorten the atrial effective refractory period and, therefore, may promote reduction in atrial wavelength and the development of multiple re-entrant atrial wavelets.[857,858] There may be multiple mechanisms of alcohol-induced atrial fibrillation, including increased sympathetic nervous system stimulation, shortening of atrial effective refractory periods, increasing interatrial electromechanical delays, and/or via vagal activity.[733,742,859,860]

Mechanisms by which the bisphosphonate drugs alendronate and zoledronic acid could cause atrial fibrillation are unclear. It has been suggested that bisphosphonate drugs may cause atrial fibrillation through the release of inflammatory cytokines,which have been associated with the development of atrial fibrillation.[750,861,862] However, bisphosphonate drugs have been shown to directly shorten atrial action potential duration and effective refractory periods, suggesting that the drugs exert direct atrial electrophysiologic effects.[863] Further study is necessary to determine the mechanism of bisphosphonate-induced atrial fibrillation and to confirm that this is truly a disease that is induced by drugs from this class.

The mechanism by which ivabradine induces atrial fibrillation is unknown. Ivabradine inhibits hyperpolarization-activated cyclic nucleotide-gated (I_f) channels in the pulmonary veins, decreasing spontaneous electrical activity; this should translate to an antiaarhythmic action rather than atrial proarrhythmia.[864] Mechanisms underlying ivabradine-induced atrial fibrillation require further investigation.

Many of the drugs that have been reported to cause atrial fibrillation or atrial flutter have commonly been used for the management of these arrhythmias. Despite the fact that flecainide has been shown to be effective for the prevention and management of atrial fibrillation, data from studies in animals indicate that flecainide may shorten atrial conduction velocity and wavelength, effects which may promote the development of atrial fibrillation.[865,866] Amiodarone-induced atrial fibrillation may, at least in some cases, be due to amiodarone-induced thyrotoxicosis.[867,868] Dobutamine has been shown to shorten atrial effective refractory periods, while theophylline has been shown to increase atrial automaticity.[869,870] Mechanisms by which other drugs may induce atrial fibrillation or flutter require further study.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The symptoms of drug-induced atrial fibrillation and atrial flutter are related to the degree of tachycardia and the resultant effect on blood pressure and cardiac output (**Table 26-15**). The symptoms of atrial fibrillation may be indistinguishable from those of atrial flutter, and, therefore, atrial fibrillation and atrial flutter must be distinguished from one another (and from other tachyarrhythmias) by ECG.

Table 26-15 Signs and Symptoms Associated with Drug-Induced Atrial Fibrillation/Flutter

- Fatigue
- Palpitations
- Dizziness
- Light-headedness
- Dyspnea
- Hypotension
- Chest pain (if underlying coronary artery disease is present)
- Heart failure symptoms
- Near-syncope
- Syncope

The onset of drug-induced atrial fibrillation or flutter is variable, depending on the inducing drug. Adenosine-induced atrial fibrillation or flutter occurs within 1 minute of administration of this extremely short-acting agent.[541] In a study of amiodarone or propafenone-induced atrial flutter, the mean (±SD) time of onset was 5 + 5.5 months after the initiation of treatment, whereas atrial flutter has been reported in association with flecainide therapy of 2 months' duration.[754,789] The duration of episodes of drug-induced atrial fibrillation or flutter is also somewhat variable; a case of albuterol-induced atrial fibrillation lasted several hours,whereas atrial flutter associated with amiodarone or propafenone may require intervention to terminate the arrhythmia.[722,754]

Sinus rhythm was the preceding rhythm in 88% of patients in whom adenosine-induced atrial fibrillation developed, whereas the remaining 12% of patients had atrial ectopic activity prior to the development of atrial fibrillation.[711] The mean ventricular rate associated with adenosine-induced atrial fibrillation was 107 + 43 bpm.[711] Adenosine-induced episodes of atrial fibrillation tend to be of short duration. The mean duration of episodes of atrial fibrillation associated with adenosine was 5.6 + 6.7 minutes (range, 8 seconds to 20.7 minutes).[711]

Conditions to consider in the differential diagnosis of drug-induced atrial fibrillation/flutter are presented in **Table 26-16**. Nondrug-induced atrial fibrillation/flutter must be considered; drug-induced atrial fibrillation/flutter is more likely in patients who are receiving drugs that have been reported to cause atrial fibrillation or flutter, particularly in patients with no known risk factors or causes for nondrug-induced atrial fibrillation/flutter, such as hypertension, ischemic heart disease, heart failure, valvular heart disease, rheumatic fever, or hyperthyroidism, or in those who have undergone thoracic surgery within the previous 2–5 days.

Table 26-16 Conditions to Consider in the Differential Diagnosis of Drug-Induced Atrial Fibrillation/Flutter

- Atrial fibrillation or flutter not induced by drugs
- Sinus tachycardia
- Atrial tachycardia
- Atrioventricular node re-entrant tachycardia
- Junctional tachycardia
- Ventricular tachycardia

RISK FACTORS

Risk factors for drug-induced atrial fibrillation or flutter have not yet been fully characterized; known risk factors are presented in **Table 26-17**. Atrial fibrillation associated with adenosine does not appear to be related to sex or age and may occur in patients with no history of atrial fibrillation.[711] Atrial fibrillation induced by adenosine is not related to the type of arrhythmia being treated.[711] Premature atrial complexes occur significantly more frequently in patients who have experienced adenosine-induced atrial fibrillation (100%) compared with those who did not (58%) and, therefore, may be somewhat predictive of impending drug-induced atrial fibrillation.[711]

Table 26-17 Risk Factors for Drug-Induced Atrial Fibrillation/Flutter

Adenosine

- Premature atrial complexes

Alcohol

- Dose >30 g daily
- Withdrawal

Amiodarone

- Left atrial hypertrophy

Dobutamine

- Advancing age
- History of atrial fibrillation
- Combined history of atrial fibrillation and heart failure

Other drugs

- Unknown

Alcohol dose is a risk factor for alcohol-induced atrial fibrillation. In one study, the mean dose of alcohol consumed during the week prior to the atrial fibrillation episode was 186 g compared with 86 g in a control population in whom alcohol-induced atrial fibrillation did not develop.[732] Another study found that the risk of alcohol-induced atrial fibrillation was increased in patients who consumed more than an average of 30 g alcohol daily.[731] The risk of alcohol-induced atrial fibrillation increases with the number of drinks consumed, with the risk greatest for those patients who consume >21 drinks weekly, although as little as 1 alcoholic drink per day may increase the risk.[746,748] Alcohol withdrawal may increase the risk of alcohol-induced atrial fibrillation.[729]

In patients receiving amiodarone for treatment of atrial fibrillation, amiodarone-induced atrial flutter does not appear to be related to age, sex, presence of structural heart disease, left ventricular function, or duration of atrial fibrillation; however, left atrial enlargement (>40 mm) may be a risk factor.[754] Independent risk factors for dobutamine-induced atrial fibrillation include advancing age (OR 1.37 [95% CI 1.13–1.65]) per 10-year increase), history of atrial fibrillation (18.4 [12.2–27.7]), and combined history of atrial fibrillation and heart failure (7.98 [4.11–15.5]).[783]

MORBIDITY AND MORTALITY

Symptoms associated with drug-induced atrial fibrillation or flutter could potentially result in hospitalization or prolonged duration of stay in a hospital or critical care unit, although prolonged duration of hospital stay as a result of drug-induced atrial fibrillation or flutter has not been reported. Drug-induced atrial fibrillation could result in stroke, but this has not yet been described. Death due to drug-induced atrial fibrillation or flutter has not been reported.

PREVENTION

For the most part, specific methods of prevention of drug-induced atrial fibrillation or atrial flutter have not been determined. However, the risk of alcohol-induced atrial fibrillation can be minimized by avoiding binge drinking and excessive doses of alcohol, by consuming less than 30 g alcohol daily, and by consuming less than 15 drinks per week (**Table 26-18**).[741,742,746] Moretti et al.[801] reported the case of a patient treated with intermittent courses of high doses of intravenous methylprednisolone for multiple sclerosis in whom recurrent atrial fibrillation attributed to the corticosteroid developed. Pretreatment prophylaxis with sotalol was ineffective, but pretreatment prophylaxis with oral propafenone 300 mg three times daily was effective at preventing methylprednisolone-induced atrial fibrillation.

Table 26-18 Approaches to Help Prevent Drug-Induced Atrial Fibrillation/Flutter

Alcohol[741,742,746]

- Avoid binge drinking/excessive doses
- Consume <30 g daily
- Consume <15 drinks per week

Methylprednisolone[801]

- Propafenone 300 mg 3 times daily

Other drugs

- Administer lowest effective dose

MANAGEMENT

The causative agent should be discontinued. In a series of cases of adenosine-induced atrial fibrillation, 67% of patients converted to sinus rhythm spontaneously, whereas 33% required cardioversion.[711] Therefore, hemodynamically stable drug-induced atrial fibrillation or atrial flutter is associated with a high incidence of spontaneous conversion, and treatment may not be necessary. In patients who do not convert spontaneously to sinus rhythm, intravenous drugs for ventricular rate control should be administered (**Table 26-19**).[853] For patients with normal left ventricular function, an intravenous β-blocker or calcium-channel blocker should be administered. Diltiazem may be preferred over verapamil as a result of a lower risk of symptomatic hypotension.[871] For patients with HFrEF, intravenous calcium-channel blockers and β-blockers should be avoided because of the risk of exacerbation of heart failure; intravenous digoxin or amiodarone should be administered instead.[853] In patients with rapid heart rates that do not respond promptly to drug therapy for ventricular rate control, or in patients with atrial fibrillation/flutter in whom symptoms are unacceptable, direct-current cardioversion should be administered. However, if atrial fibrillation has been present for >48 hours, or if the duration of the episode of atrial fibrillation is unknown, patients should undergo transesophageal echocardiography to rule out an atrial thrombus before electrical or pharmacologic cardioversion is performed.

After the administration of agents to control the ventricular rate, drug-induced atrial fibrillation or flutter should be converted to sinus rhythm, using either elective direct-current cardioversion or pharmacologic cardioversion. Acceptable agents for pharmacologic cardioversion include amiodarone, dofetilide, flecainide, ibutilide, or propafenone (Table 26-19). If the atrial fibrillation was induced by a sodium channel blocking agent, conversion to sinus rhythm should be achieved using direct-current cardioversion or ibutilide. It should be noted, however, that the effectiveness of antiarrhythmic drug therapy for drug-induced atrial fibrillation or atrial flutter has not been studied.

Table 26-19 Treatment Options for Drug-Induced Atrial Fibrillation[853]

DISCONTINUE THE OFFENDING AGENT

Drug/Treatment	**Recommended Doses**
Ventricular rate control in patients with normal left ventricular function	
Esmolol	*Loading dose:* 500 mcg/kg IV over 1 minute
	Maintenance infusion: 50–300 mcg/kg/min IV
Metoprolol	2.5–5 mg IV bolus over 2 minutes; up to 3 doses at 10-minute intervals
Propranolol	1 mg IV over 1 minute; up to 3 doses at 2-minute intervals
Diltiazem	*Loading dose:* 0.25 mg/kg IV over 2 minutes
	Maintenance infusion: 5–15 mg/hr IV
Verapamil	0.075–0.15 mg/kg IV over 2 minutes
	If necessary, administer an additional dose of 10 mg 30 minutes later
Ventricular rate control in patients with heart failure with reduced ejection fraction	
Amiodarone	*Loading dose:* 300 mg IV over 1 hour
	Maintenance infusion: 10–50 mg/hr IV for up to 24 hours
Conversion to sinus rhythm	
Direct-current cardioversion	100 Joules, escalating if necessary
Amiodarone[a]	*Loading dose:* 150 mg IV over 10 minutes
	Maintenance dose: 1 mg/min continuous IV infusion for 6 hours, then 0.5 mg/min continuous IV infusion for 18 hours
Dofetilide	*CrCL >60 mL/min:* 500 mcg orally twice daily *CrCL 40–60 mL/min:* 250 mcg orally twice daily *CrCL 20–40 mL/min:* 125 mcg orally twice daily *CrCL <20 mL/min:* contraindicated
Flecainide[a]	200–300 mg single oral dose
Ibutilide	1 mg IV over 10 minutes; repeat with a second 1-mg dose 10 minutes after the first dose if atrial fibrillation persists
Propafenone[a]	600 mg single oral dose

CrCL = creatinine clearance, IV = intravenously.

[a]If the cause of the atrial fibrillation is a sodium channel-blocking drug (amiodarone, flecainide, propafenone), avoid the use of additional sodium channel-blocking agents and administer direct-current cardioversion or ibutilide. If the atrial fibrillation is caused by theophylline toxicity, administer activated charcoal 50–100 g, followed by 50 g q 4 hr. Alternatively, continuous hemodialysis with filtration may be performed.

In patients with atrial fibrillation in whom new atrial flutter induced by amiodarone or propafenone develops, radiofrequency catheter ablation of the isthmus between the tricuspid annulus and the inferior vena cava has been used to terminate the atrial flutter while allowing patients to remain on antiarrhythmic drug therapy for the management of the atrial fibrillation.[754,755] Radiofrequency catheter ablation of drug-induced atrial flutter is successful in 90–100% of patients, and drug-induced atrial flutter did not recur in 14 of 15 patients during a 1-year follow-up period.[754]

If the drug-induced atrial fibrillation is a result of a theophylline overdose, activated charcoal may be administered.[872] Alternatively, continuous hemodialysis with filtration may be performed.[827]

Table 26-20 Agents Implicated in Drug-Induced Atrial Tachycardia

Drug	Incidence	Level of Evidence[a]
Albuterol[721]	NK	C
Caffeine[874-876]	NK	C
Digoxin[148,877-889]	0–4%	B
Phenylpropanolamine[875]	NK	C
Terbutaline[890]	NK	C
Theophylline[822,890-895]	0–16%[b]	B

[a]Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b]Incidence increases with increasing serum theophylline concentration.

INFORMATION FOR PATIENTS

Patients who are taking drugs known to cause atrial fibrillation or flutter should be instructed that the medication, in rare instances, may cause the heart rate (pulse) to become faster. Patients should take their pulse daily and should be instructed to consult their pharmacist or physician if the heart rate increases to above 100–120 bpm, or if they feel palpitations, light-headed, dizzy, fatigued, weak, short of breath, or experience chest pain.

ATRIAL TACHYCARDIA

Atrial tachycardia is a supraventricular arrhythmia that is characterized on ECG by discrete P-waves and narrow or normal QRS duration, at a rate usually between 100 and 250 bpm.[873] There are two primary types of atrial tachycardia: focal atrial tachycardia (which will be referred to simply as atrial tachycardia), in which the arrhythmia is initiated at a single localized atrial focus, and multifocal atrial tachycardia, in which there are multiple atrial foci. Focal atrial tachycardia is characterized by regular intervals between QRS complexes on ECG, whereas multifocal atrial tachycardia is associated with irregular QRS intervals and three or more P-wave morphologies.[873] Atrial tachycardia may occur intermittently, which is commonly referred to as paroxysmal atrial tachycardia.

CAUSATIVE AGENTS

Drugs that have been reported to cause atrial tachycardia are listed in **Table 26-20**.[148,721,822,874-895]

EPIDEMIOLOGY

Paroxysmal atrial tachycardia is often described as a characteristic arrhythmia associated with digoxin toxicity.[885] However, at one large urban medical center, “definite” paroxysmal atrial tachycardia was documented in only 2% of 219 patients with a discharge diagnosis of digoxin intoxication.[148] In this analysis, paroxysmal atrial tachycardia occurred less frequently than any other arrhythmia associated with digoxin intoxication. Therefore, despite the commonly held belief that paroxysmal atrial tachycardia is commonly associated with digoxin toxicity, it appears to occur relatively rarely.

The incidence of multifocal atrial tachycardia associated with theophylline is dependent on serum theophylline concentrations.[895] In an analysis of 100 patients receiving theophylline, atrial tachycardia did not occur in the patients with serum theophylline concentrations <10 mcg/mL. However, in patients with serum theophylline concentrations between 10 and 20 mcg/mL, the incidence of atrial tachycardia was 8%, and the incidence rose to 16% in patients with serum theophylline concentrations >20 mcg/mL.[895]

MECHANISMS

Mechanisms of drug-induced atrial tachycardia are not entirely clear, but are likely related to increasing the automaticity of atrial tissue (**Table 26-21**).[873] This may occur because of β-receptor stimulation associated with drugs such as albuterol or terbutaline or through phosphodiesterase inhibition and the resulting elevated concentrations of cyclic adenosine monophosphate associated with caffeine or theophylline.

Table 26-21 Mechanisms of Drug-Induced Atrial Tachycardia

Drug	Mechanism
Albuterol, terbutaline	Stimulation of β-receptors, leading to enhanced atrial automaticity
Caffeine, theophylline	Phosphodiesterase inhibition, leading to increased plasma concentrations of cyclic adenosine monophosphate, resulting in enhanced atrial automaticity
Digitalis glycoside toxicity	Extreme inhibition of the sodium–potassium–adenosine triphosphatase pump, leading to markedly increased myocyte concentrations of sodium, which are exchanged with calcium, ultimately resulting in markedly increased myocyte calcium concentrations, promoting enhanced atrial automaticity

The mechanism of paroxysmal atrial tachycardia with AV nodal blockade associated with digitalis glycoside toxicity is likely related to profound inhibition of the sodium–potassium–adenosine triphosphatase pump. This leads to markedly increased myocyte sodium concentrations, which in turn are exchanged with calcium, ultimately resulting in markedly increased myocyte concentrations of calcium. This promotes enhanced atrial automaticity due to delayed phase-4 repolarization in the atrial action potential.[896]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The symptoms of drug-induced atrial tachycardia are related to heart rate and the resultant effect on blood pressure and cardiac output (**Table 26-22**). The diagnosis of drug-induced atrial tachycardia must be made primarily on the basis of the appearance on ECG. Conditions to consider in the differential diagnosis of drug-induced atrial tachycardia are presented in **Table 26-23**.

Table 26-22 Signs and Symptoms Associated with Drug-Induced Atrial Tachycardia

- Palpitations
- Fatigue
- Dizziness
- Light-headedness
- Shortness of breath
- Chest pain (if underlying coronary artery disease is present)
- Near-syncope
- Syncope

Table 26-23 Conditions to Consider in the Differential Diagnosis of Drug-Induced Atrial Tachycardia

- Atrial fibrillation
- Atrial flutter
- Atrial tachycardia not induced by drugs
- Sinus tachycardia
- AV nodal re-entrant tachycardia
- Junctional tachycardia
- Ventricular tachycardia

AV = atrioventricular.

Table 26-24 Risk Factors for Drug-Induced Atrial Tachycardia

Digoxin

- Serum digoxin concentrations >2 ng/mL
- Kidney disease
- Drug interactions leading to elevated serum digoxin concentrations
- Hypomagnesemia

Theophylline

- Serum theophylline concentrations >20 mcg/mL

RISK FACTORS

Risk factors for drug-induced atrial tachycardia are presented in **Table 26-24**. Paroxysmal atrial tachycardia with AV block is extremely rare at therapeutic serum digoxin concentrations but occurs primarily when serum digoxin concentrations increase to >2 ng/mL. Therefore, risk factors for digoxin-induced paroxysmal atrial tachycardia with AV block are the same as those for digoxin toxicity. Because digoxin is cleared primarily by the kidneys, renal dysfunction is a primary risk factor for digoxin toxicity and digoxin-induced atrial tachycardia with AV block. In addition, drug interactions that result in increased serum digoxin concentrations enhance the risk of digoxin-related arrhythmias. Amiodarone, verapamil, and quinidine are known to significantly increase serum digoxin concentrations.[690-692]

Paroxysmal atrial tachycardia with AV block associated with digitalis toxicity may occur in patients across a wide range of ages. In one series, in which 31 cases of paroxysmal atrial tachycardia with AV block were reported in association with digitoxin, the age range of patients varied from 20 to 73 years (average, 52).[878] There were 15 women and 16 men, with a variety of underlying cardiovascular disorders, including valvular heart disease ($n = 14$), congenital heart diseases ($n = 6$), and ischemic heart disease ($n = 1$).[878] Although digoxin-induced atrial tachycardia most commonly occurs in patients with digoxin toxicity, it has been reported in patients with therapeutic serum digoxin concentrations who are hypomagnesemic.[889] As mentioned previously, elevated serum theophylline concentration is a risk factor for theophylline-induced atrial tachycardia. New supraventricular arrhythmias including multifocal atrial tachycardia were reported in seven patients with serum theophylline concentrations between 21 and 40 mcg/mL.[894]

MORBIDITY AND MORTALITY

Patients with paroxysmal atrial tachycardia with AV block may present to the emergency department and require hospitalization for management of digoxin toxicity. The incidence of mortality associated with digitalis-induced paroxysmal atrial fibrillation and AV block has not been reported, but is likely extremely low. In the series of 31 patients with digitoxin-induced paroxysmal atrial tachycardia, two patients died, but neither death appears to have been related to the arrhythmia or the digitoxin toxicity.[878] Patients with atrial tachycardia associated with other drugs may also present to the emergency department for treatment, particularly in the event of theophylline toxicity.

PREVENTION

Digoxin-associated paroxysmal atrial tachycardia with AV nodal blockade is usually preventable by maintaining serum digoxin concentrations <2 ng/mL (**Table 26-25**). Measurement of serum digoxin concentrations is therefore recommended in patients who may be at risk for elevated concentrations, including patients with kidney disease or changing kidney function and those receiving concomitant therapy with drugs known to increase serum digoxin concentrations (particularly amiodarone, verapamil, or quinidine). In patients with kidney disease, appropriate dose adjustment should be made. In general, patients with calculated creatinine clearance ≤20 mL/min should receive an initial reduced digoxin dose of 0.125 mg daily.[897,898] In patients with calculated creatinine clearance <20 mL/min who are receiving concomitant therapy with drugs known to inhibit the elimination of digoxin, the initial digoxin dose should be 0.125 mg every other day. In patients taking digoxin, serum potassium and magnesium concentrations should be maintained within the normal range.

Atrial tachycardia associated with theophylline may be prevented by maintaining serum theophylline concentrations <20 mcg/mL.

Table 26-25 Approaches to Help Prevent Drug-Induced Atrial Tachycardia

Digoxin

- Maintain serum digoxin concentrations <2 ng/mL
- Appropriate dose adjustment for kidney disease
- Appropriate dose adjustment in the presence of interacting drugs, particularly amiodarone, verapamil, or quinidine
- Maintain normal serum magnesium concentration

Theophylline

- Maintain serum theophylline concentrations <20 mcg/mL

MANAGEMENT

Treatment options for drug-induced atrial tachycardia are presented in **Table 26-26**. Digoxin-associated paroxysmal atrial tachycardia with AV nodal block should be managed by withholding digoxin therapy until serum digoxin concentrations decline to <2 ng/mL. Because paroxysmal atrial tachycardia with AV block is rarely life-threatening, it is usually not necessary to administer digoxin immune antibody fragments. In the very rare event that the arrhythmia is hemodynamically unstable, synchronized direct-current cardioversion should be used to terminate the arrhythmia. Attempts to sedate the patient should be made, unless the urgency of the situation does not permit. Initial cardioversion energy should be 50–100 J for focal atrial tachycardia and 120–200 J biphasic or 200 J monophasic for multifocal atrial tachycardia. Following the conversion of hemodynamically unstable paroxysmal atrial tachycardia with AV block, digoxin immune antibody fragments should be administered to prevent recurrence of the hemodynamically unstable arrhythmia.

Table 26-26 Management of Drug-Induced Atrial Tachycardia

DISCONTINUE THE OFFENDING AGENT

Hemodynamic Stability	**Recommended Doses**
Hemodynamically unstable	Synchronized DC cardioversion (initial energy 50–100 J, focal atrial tachycardia; 120–200 J biphasic shock or 200 J monophasic shock for multifocal atrial tachycardia) *If due to digoxin toxicity:* Administer digoxin immune antibody fragments. The dose is based on the serum digoxin concentration: Number of 38-mg vials = serum digoxin concentration × weight (kg) = 100. *If the arrhythmia is a result of an acute digoxin overdose and the amount of digoxin ingested is known, the dose of digoxin immune antibody fragments should be calculated as follows:* Number of 38-mg vials = mg digoxin ingested acutely × 0.8 = 0.5. *If due to theophylline toxicity:* Administer activated charcoal: 50–100 g, followed by 50 g q 4 hr
Hemodynamically stable focal atrial tachycardia	Esmolol 500 mcg IV bolus over 1 minute, followed by 50–300 mcg/kg/min, with repeated boluses between each dose increase Or Metoprolol 2.5–5 mg IV bolus over 2 minutes; can repeat 2.5–5 mg IV bolus in 10 minutes, up to 3 doses Or Propranolol 1 mg IV over 1 minute; can repeat 1 mg IV at 2-minute intervals, up to 3 doses Or Diltiazem 0.25 mg/kg IV bolus over 2 minutes, followed by infusion at 5–10 mg/hr Or Verapamil 5–10 mg (0.075–0.15 mg/kg) IV bolus over 2 minutes; if no response, administer an additional 10 mg (0.15 mg/kg) 30 minutes after the first dose, then infusion at 0.005 mg/kg/min **For patients with HFrEF:** Adenosine 6 mg rapid IV injection bolus, administered over 1–2 seconds, followed by rapid saline flush; if no response within 1–2 minutes, administer 12 mg IV rapid bolus; a second 12 mg dose can be administered if necessary
Hemodynamically stable multifocal atrial tachycardia	IV metoprolol or verapamil at doses recommended above

DC = direct current, HFrEF = heart failure with reduced ejection fraction, IV = intravenous.

Hemodynamically stable drug-induced atrial tachycardia should be managed with intravenous β-blockers, diltiazem or verapamil.[873,892] Drug-induced atrial tachycardia may also be responsive to treatment with adenosine.[873] In patients with drug-induced atrial tachycardia who have HFrEF and are unresponsive to adenosine, intravenous amiodarone may be administered. If the drug-induced atrial tachycardia is a result of a theophylline overdose, activated charcoal may administered.[872] For patients with drug-induced multifocal atrial tachycardia, therapy with intravenous metoprolol or verapamil is recommended.[873]

INFORMATION FOR PATIENTS

Patients who are taking drugs that are known to cause atrial tachycardia should be instructed that the drug may in rare cases cause the heart rate (pulse) to become faster. Patients should be taught to take their pulse and to monitor their heart rate daily. Patients should be instructed to consult their pharmacist or physician if the heart rate increases above 100–120 bpm or if they feel light-headed, dizzy, tired, weak, or short of breath, or experience chest pain.

AV NODE RE-ENTRANT TACHYCARDIA

AV node re-entrant tachycardia (AVNRT) is the most common form of the group of arrhythmias commonly referred to as paroxysmal supraventricular tachycardia. AVNRT is characterized on ECG by regular, narrow QRS complexes, often with an absence of discernible P-waves.[873]

CAUSATIVE AGENTS

Drugs that have been associated with AVNRT are listed in **Table 26-27**.[721,771,772,782,824,892,894,899-939]

Table 26-27 Agents Implicated in Drug-Induced Atrioventricular Node Re-entrant Tachycardia

Drug	Incidence	Level of Evidence[a]
Albuterol[721,899-908]	0–21%[b]	A
Caffeine[909-912,c]	NK	C
Carbamazepine[913]	NK	C
Clozapine[911,914,915]	NK	C
Dobutamine[771,772,782,916-929]	0–12%	A
Enoximone[916]	NK	A
Fluoxetine[930, 931]	NK	C
Furosemide[932]	NK	C
Ipratropium[933,934]	0.5%	A

Methylprednisolone[935,936]	NK	C
Phenylpropanolamine[937]	NK	C
Theophylline[721,824,892,894,899,938,939]	NK[b]	C

NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Incidence reported to be up to 76% in patients receiving concomitant therapy with albuterol and theophylline.

[c] Suicide attempt or overdose, 2.7–35 g caffeine ingested; one case with intravenous caffeine administration, one case with intradermal caffeine administration.

EPIDEMIOLOGY

The incidence of drug-induced AVNRT is largely unknown. The incidences of AVNRT associated with albuterol, dobutamine, and ipratropium are presented in Table 26-27.

MECHANISMS

Mechanisms of drug-induced AVNRT are somewhat unclear. Nondrug-related AVNRT was previously thought to be caused by a re-entrant circuit involving the AV node, in which there is antegrade conduction over the slow-conducting portion of the circuit and retrograde conduction over the faster-conducting portion.[940,941] However, it is now recognized that the re-entrant circuit often is not confined to the AV node, but involves perinodal tissue.[873] AV nodal or perinodal re-entry is usually initiated by a premature atrial impulse that “uncovers” the latent re-entrant circuit by creating the circumstances required for re-entry, namely, unidirectional block in the fast pathway and further slowing of impulse conduction down the slow pathway. Therefore, it is possible that drugs that cause AVNRT do so by stimulating premature atrial depolarizations that provoke AV nodal re-entry. In cases of AVNRT that occurred in association with continuous furosemide infusions in infants or children after cardiac surgery, the authors speculated that a rapid change in intravascular volume may have contributed to the development of the arrhythmias, possibly as a result of intercompartmental electrolyte shifts.[932] Overall, the mechanisms by which drug-induced AVNRT occurs have not been determined but are likely related to stimulation of premature atrial depolarizations, alterations in AV nodal conduction velocity or repolarization, or both.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The symptoms of drug-induced AVNRT are similar to those of other tachyarrhythmias (**Table 26-28**) and are related to heart rate and the resultant effect on blood pressure and cardiac output. Ventricular rates associated with drug-induced AVNRT can be quite fast, ranging from 150 to 300 bpm.[931,932,937] Conditions to consider in the differential diagnosis of drug-induced AVNRT are presented in **Table 26-29**. The diagnosis of AVNRT must be made primarily on the basis of the appearance of the rhythm on ECG.

Table 26-28 Signs and Symptoms Associated with Drug-Induced Atrioventricular Node Re-entrant Tachycardia

- Palpitations
- Dizziness
- Fatigue
- Light-headedness
- Shortness of breath
- Chest pain (if underlying coronary artery disease is present)
- Near-syncope
- Syncope

Table 26-29 Conditions to Consider in the Differential Diagnosis of Drug-Induced Atrioventricular Node Re-entrant Tachycardia

- Atrial fibrillation
- Atrial flutter
- Atrial tachycardia
- Sinus tachycardia
- Junctional tachycardia
- AV nodal re-entrant tachycardia not induced by drugs
- Ventricular tachycardia

AV = atrioventricular.

RISK FACTORS

Known or potential risk factors for drug-induced AVNRT are presented in **Table 26-30**. Albuterol-induced AVNRT appears to be more likely in patients receiving the drug intravenously, particularly at infusion rates >60 mcg/min.[890,900] AVNRT associated with dobutamine occurs more commonly in men than in women and in elderly patients.[774,921,922] In addition, severity of myocardial ischemia has been shown to be an independent predictor of dobutamine-induced AVNRT; in a study of 1,076 patients undergoing dobutamine stress myocardial perfusion imaging, the mean myocardial infarction score (calculated based on assessment of fixed perfusion defects during myocardial perfusion scintigraphy) was 4.4 ± 4.1 in patients with AVNRT, as compared with 2.8 ± 3.5 in those without it, and the infarction score was an independent predictor of AVNRT.[922]

Table 26-30 Risk Factors for Drug-Induced Atrioventricular Node Re-entrant Tachycardia

Albuterol

- Continuous intravenous infusion
- Intravenous infusion rate >60 mcg/min
- Concomitant therapy with theophylline

Dobutamine

- Male sex
- Elderly
- Myocardial infarction score on dobutamine stress test

Furosemide

- Reported only in infants or children following cardiac surgery
- Continuous infusion resulting in profound diuresis (8–10 mL/kg/hr)

Theophylline

- Serum theophylline concentrations >20 mcg/mL
- Concomitant therapy with albuterol

All of the reported cases of AVNRT associated with continuous furosemide infusions (*n* = 3 patients) have occurred in infants or children after cardiac surgery. In these patients, the arrhythmia occurred within 3–7 hours after the initiation of a furosemide infusion of 1 mg/kg/hr. A common factor in these three patients was substantial diuresis resulting from the furosemide, in the range of 8–10 mL/kg/hr, as compared with an average fluid elimination of 2.5 mL/kg/hr in 22 other patients who had received a similar furosemide infusion.[932] Serum potassium concentration was below normal limits in one of the three patients in whom the arrhythmia developed but remained normal in the other two cases. Therefore, it is possible that a large amount of fluid loss may be a risk factor or predictor of drug-induced AVNRT in infants or children receiving a continuous infusion of furosemide after cardiac surgery. Serum theophylline concentration is a risk factor for theophylline-induced supraventricular arrhythmias; new supraventricular arrhythmias were reported in seven patients with serum theophylline concentrations between 21 and

40 mcg/mL.[894] Risk factors for AVNRT associated with other drugs have not been identified.

MORBIDITY AND MORTALITY

Drug-induced AVNRT may result in symptoms sufficient to result in presentation to the emergency department and hospitalization.[909,910,930,934] In addition, drug-induced AVNRT may result in prolongation of stays in the intensive care unit and the hospital.[931,932] Mortality associated with drug-induced AVNRT is likely quite rare.

PREVENTION

The likelihood of albuterol-induced AVNRT may be reduced by avoiding continuous intravenous infusions at doses >60 mcg/min (**Table 26-31**). Combinations of drugs that may induce AVNRT should be avoided, particularly the concomitant administration of albuterol and theophylline. In the cases of furosemide-induced AVNRT in infants and children after cardiac surgery, substantial fluid elimination appears to have been a risk factor, and in that population, avoidance of diuresis of volumes >2.5 mL/kg/hr over periods of 3–7 hours may minimize the risk.[932] Maintaining serum theophylline concentrations <20 mcg/mL reduces the risk of theophylline-induced supraventricular arrhythmias.

Table 26-31 Approaches to Help Prevent Drug-Induced Atrioventricular Node Re-entrant Tachycardia

Albuterol

- Avoid continuous intravenous infusions at rate >60 mcg/min
- Avoid concomitant therapy with theophylline

Furosemide

- Avoid diuresis of volumes >2.5 mL/kg/hr over periods of 3–7 hr in infants/children after cardiac surgery

Theophylline

- Maintain serum theophylline concentrations <20 mcg/ mL
- Avoid concomitant therapy with albuterol

MANAGEMENT

Management options for drug-induced AVNRT are presented in **Table 26-32**. As with other drug-induced arrhythmias, initial management of drug-induced AVNRT is discontinuation of therapy with the offending agent. If the patient is hemodynamically unstable, synchronized direct-current cardioversion should be administered, using an initial energy of 50–100 J.[695] Sedation of the patient is always preferred unless hemodynamic instability is so severe that there is no time for sedation.

In patients who are hemodynamically stable, drug-induced AVNRT may respond to agents typically used to treat nondrug-induced AVNRT.[873] Adenosine has been found to be effective for AVNRT associated with albuterol and may be used as a drug of first choice for hemodynamically stable AVNRT.[873,903,907] Intravenous verapamil 2.5 mg has been effective for terminating AVNRT associated with fluoxetine.[931]

INFORMATION FOR PATIENTS

Patients who are taking drugs that may cause AVNRT should be instructed that the medication may, in rare instances, cause the heart rate (pulse) to become faster. Patients should be instructed to take their pulse daily and to consult their pharmacist or physician if the heart rate increases to above 100–120 bpm, or if they feel palpitations, light-headed, dizzy, tired, weak, or short of breath, or experience chest pain.

Table 26-32 Management Options for Drug-Induced Atrioventricular Node Re-entrant Tachycardia[873]

In hemodynamically unstable patients:	In hemodynamically stable patients:
Discontinue the offending agent Synchronized DC cardioversion (initial energy 50–100 J)	Discontinue the offending agent Vagal maneuvers (cough, carotid sinus massage, Valsalva) Adenosine 6 mg IV rapid bolus, followed by saline flush If no response within 2 minutes, adenosine 12 mg IV rapid bolus, followed by saline flush; can administer a second 12 mg dose if necessary If no response to adenosine and patient has LVEF >40% and/or no history of HFrEF: IV β-blocker, diltiazem or verapamil at doses listed in Table 26-26 If no response to IV β-blocker, diltiazem or verapamil: synchronized DC cardioversion

	If no response to adenosine in patient with HFrEF: synchronized DC cardioversion

DC = direct current, HFrEF = heart failure with reduced ejection fraction, IV = intravenous, J = Joules, LVEF = left ventricular ejection fraction.

CHAPTER 27

Hypertension

Liza W. Claus and Joseph J. Saseen

More than 80 million Americans have hypertension, or approximately one out of three adults.[1] Hypertension is a chronic medical condition that is characterized by persistent increases in systolic or diastolic blood pressure, or both. The term *elevated blood pressure* has replaced the category formerly known as prehypertension and is used to identify patients with blood pressures higher than normal but not yet to the threshold diagnostic for hypertension.[2] Hypertension is elevated blood pressure nearly always asymptomatic. Target organ damage (e.g., coronary artery disease, chronic kidney disease/failure, ischemic stroke), commonly presenting as a cardiovascular event, is the primary cause of associated morbidity and mortality in patients with hypertension.[2] Most patients (90–95%) with hypertension have primary (also known as essential) hypertension. The remainder have secondary hypertension, which includes patients with drug-induced causes.

CAUSATIVE AGENTS

Drug-induced hypertension is defined as high blood pressure caused by using (or discontinuing the use of) a chemical substance, drug, or medication.[3] Expert reviews of drug-induced hypertension are available, but do not thoroughly evaluate published literature to support the association between a comprehensive list of cited drugs and drug-induced hypertension.[4,5] Drugs that have been reported to cause hypertension are listed in **Table 27-1**.[6-108] Drugs on this list are also identified as potential causes of resistant hypertension.[109] There are some limitations to this list. Adverse drug effect reporting often identifies increases in blood pressure, not always drug-induced hypertension per se. Therefore, for many drugs that have been reported to increase blood pressure, the incidence of drug-induced hypertension may be unknown. This list also represents agents that are used primarily for chronic conditions or that are used for a prolonged period of time. These medications may cause hypertension, exacerbate previously well-controlled hypertension, or antagonize the effects of antihypertensive pharmacotherapy.

EPIDEMIOLOGY

Hypertension is one of the most common chronic medical conditions. Despite increased public awareness, the prevalence of hypertension is not declining. Over 30% of the American population has hypertension.[110] With the introduction of the 2017 American College of Cardiology (ACC)/American Heart Association (AHA)/American Academy of Physician Assistants (AAPA)/Association of Black Cardiologists (ABC)/American College of Preventive Medicine (ACPM)/American Geriatrics Society (AGS)/American Pharmacists Association (APhA)/American Society of Hypertension (ASH)/American Society for Preventive Medicine (ASPM)/National Medical Association (NMA)/Preventive Cardiovascular Nurses Association (PCNA) Guideline for the Prevention, Detection, Evaluation, and Management of High Blood Pressure in Adults and its lower blood pressure thresholds (**Table 27-2**), it is now estimated that a substantially higher number of patients will be diagnosed with hypertension.[2,111] Although most patients who truly have hypertension are aware of their condition (greater than 80%), only two-thirds of these patients are treated for hypertension, and just over half have controlled blood pressure values.[1] When considering these statistics, the potential impact of drug-induced hypertension is significant, as many patients in whom drug-induced hypertension develops may not be identified or appropriately treated. Although the precise incidence of drug-induced hypertension in the general population is unknown, it is reasonable to assume that drugs may cause some undiagnosed cases of hypertension. The prevalence of drug-induced hypertension is possibly very low, but drug-induced exacerbations of hypertension are likely more common.

Table 27-1 Agents Implicated in Drug-Induced Hypertension

Drug	Incidence[a]	Level of Evidence[b]
Amphetamines[6,7]	NK	A
Antihypertensive agents[8-27,c]	NK	B
Bevacizumab[28-32]	8–18%	A
Bupropion[33-35]	2–6.1%	B
Caffeine[36]	NK	B
Celecoxib[37-42]	2.4–12.5%	A
Cocaine[43]	NK	C
Corticosteroids[44-49]	NK	A
Cyclosporine[50-56]	11.2–50%	A
Darbepoetin-α[57]	23%	A
Desvenlafaxine[58]	1.3–2.3%	A
Ephedra alkaloids[59-61]	NK	B
Ergot alkaloids[62]	NK	C
Erythropoetin-α[63,64]	24%	A
Estrogen-containing oral contraceptives[65-71]	5%	A
Ivabradine[72]	8.9%	A
Licorice[73-75]	NK	C
Monoamine oxidase inhibitors[76,77,d]	NK	C
NSAIDs[78-83]	NK	A
Phenylephrine[84,85]	NK	C
Pseudoephedrine[86-90]	NK	A
Sibutramine[91-96]	NK	A
Sorafenib[97,98]	17%	A
Sunitinib[99-101]	15–30%	A
Tacrolimus[102-104]	47–50%	A
Testosterone[105,106]	3%	A
Venlafaxine[107,108]	3–13%	A

NK = not known, NSAID = nonsteroidal anti-inflammatory drug.

[a] Based on reported incidence of hypertension or persistent blood pressure elevation, not just increase in blood

pressure, from product information or literature (not placebo-corrected).

[b] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[c] When therapy is abruptly discontinued.

[d] Result of a drug–food interaction with tyramine-containing foods or a drug–drug interaction.

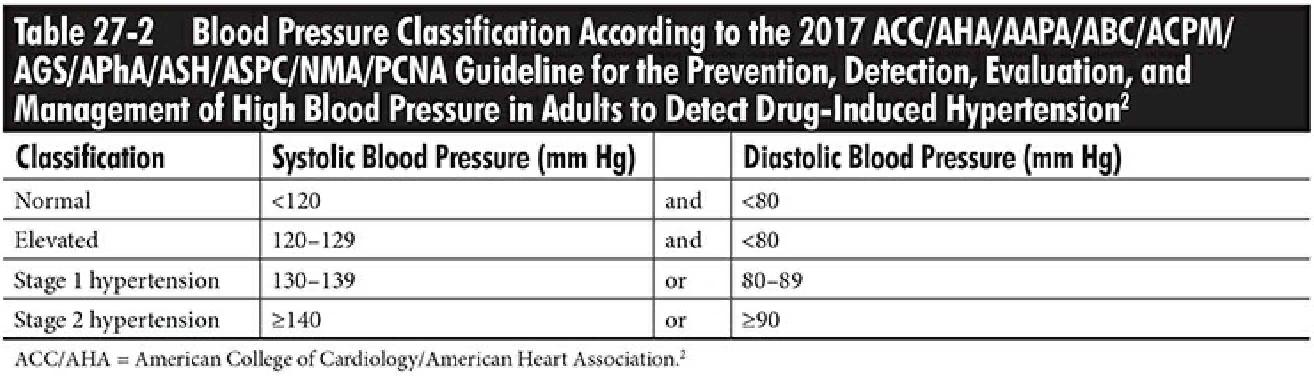

Table 27-2 Blood Pressure Classification According to the 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA Guideline for the Prevention, Detection, Evaluation, and Management of High Blood Pressure in Adults to Detect Drug-Induced Hypertension[2]

Classification	Systolic Blood Pressure (mm Hg)		Diastolic Blood Pressure (mm Hg)
Normal	<120	and	<80
Elevated	120–129	and	<80
Stage 1 hypertension	130–139	or	80–89
Stage 2 hypertension	≥140	or	≥90

ACC/AHA = American College of Cardiology/American Heart Association.[2]

The 2017 ACC/AHA Hypertension Guideline identifies medications that can cause hypertension.[2] This chapter expands on the list provided by the 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA Guideline for the Prevention, Detection, Evaluation, and Management of High Blood Pressure in Adults to include additional drugs.[2] These agents may either cause hypertension or be a reason for resistant hypertension.[109] Estimated incidences of drug-induced hypertension associated with specific agents are also presented in Table 27-1. The exact incidence of drug-induced hypertension associated with several agents is unknown; however, these medications have been shown to increase blood pressure.

MECHANISMS

Arterial blood pressure is regulated by several factors: the adrenergic nervous system, the renin–angiotensin–aldosterone system, kidney function and blood flow, hormonal regulatory systems (adrenal cortical hormones, vasopressin, thyroid, insulin), and the vascular endothelium (nitric oxide, bradykinin, prostacyclin, endothelin).[5,112] Drug-induced alterations of these systems may explain persistent increases in blood pressure associated with certain agents. The various mechanisms by which drugs may induce hypertension (**Table 27-3**) are broadly categorized as stimulation of sympathetic nervous system activity, fluid-volume expansion, interference with the action of antihypertensive drugs, paradoxical responses to antihypertensive agents, and unknown mechanisms.[5]

SYMPATHETIC NERVOUS SYSTEM STIMULATION

Certain drugs (e.g., cocaine, amphetamines, ephedra, some antidepressants) can activate the sympathetic nervous system through norepinephrine or norepinephrine-like stimulation. Stimulation of peripheral adrenergic α-receptors causes vasoconstriction, while stimulation of myocardial adrenergic β-receptors increases heart rate and contractility, both of which can increase blood pressure. Under normal circumstances, compensatory mechanisms are triggered that decrease total peripheral resistance, which usually maintains normal blood pressure. However, drugs that cause hypertension may blunt or impair this compensatory response.

Table 27-3 Mechanisms of Drug-Induced Hypertension

Drug	Mechanism
Amphetamines Caffeine Cocaine Desvenlafaxine Ergot alkaloids (ergonovine, methysergide) Phenylephrine–ophthalmic Pseudoephedrine Sibutramine Venlafaxine	Increased stimulation of sympathetic nervous system activity
Antivascular endothelin growth factor agents	Possible mechanism: endothelin damage secondary to decreased nitric oxide release and release of growth factors that stimulate the renin–angiotensin–aldosterone system
β-blockers Centrally acting α-agonists	Abrupt discontinuation, causing overstimulation of α- and/or β-receptors
Calcineurin inhibitors (cyclosporine, tacrolimus)	Increased prostaglandin production resulting in decreases in sodium, water, and potassium excretion, causing increased fluid-volume expansion
Corticosteroids Licorice	Stimulation of the mineralocorticoid receptor, causing increased fluid-volume expansion
Erythropoiesis-stimulating agents	Supratherapeutic effects of increasing blood cell production, causing increased fluid volume
Estrogen-containing oral contraceptives	Increased hepatic production of angiotensinogen, causing stimulation of the renin–angiotensin–aldosterone system
Monoamine oxidase inhibitors	Overall stimulation of sympathetic nervous system activity by increased production of adrenergic substances secondary to ingesting tyramine-containing foods or a drug interaction
NSAIDs and COX-2 inhibitors	Inhibition of prostaglandins, causing vasoconstriction and stimulation of the renin–angiotensin–aldosterone system, resulting in increased fluid-volume expansion
Testosterone	Increased fluid-volume expansion; stimulation of sympathetic nervous system activity

COX = cyclooxygenase, NSAID = nonsteroidal anti-inflammatory drug.

FLUID-VOLUME EXPANSION

The renin–angiotensin–aldosterone system functions with the kidneys to regulate arterial blood pressure. Decreases in blood pressure or kidney blood flow, volume depletion, or sodium depletion all increase renin secretion from the kidney. Renin mediates the transformation of angiotensinogen to angiotensin I, which is converted by angiotensin-converting enzyme to angiotensin II. Angiotensin II is a potent direct vasoconstrictor that stimulates production of aldosterone, which causes sodium and water retention. Several drugs (e.g., nonsteroidal anti-inflammatory drugs [NSAIDs], including the cyclooxygenase-2 [COX-2] selective inhibitor celecoxib, certain immunosuppressants) can indirectly trigger renin release, primarily by decreasing kidney perfusion.[113,114] In premenopausal women, estrogens have been shown to stimulate the renin–angiotensin–aldosterone system by increasing hepatic production of angiotensinogen.[115,116] These effects are normally overcome by negative-feedback mechanisms that prevent excessive renin release. However, this may not occur in patients taking drugs known to induce hypertension or in patients with chronic kidney disease or cardiovascular risk factors. Generalized vasoconstriction, especially in the kidney, is the hypothesized cause of cyclosporine-induced hypertension.[50,117]

Certain drugs that alter hormonal regulation (e.g., oral contraceptives, corticosteroids) can cause hypertension. The estrogen component of oral contraceptives is primarily responsible for blood-pressure elevation, but the mechanism is unclear. In premenopausal women, oral contraceptive use results in serum estrogen and progestin concentrations that are higher than those that result from endogenous hormone production. This is in sharp contrast to the use of estrogen-replacement therapy (ERT) or hormone-replacement therapy (HRT) in postmenopausal women, during which serum estrogen and progestin concentrations are lower than those associated with premenopausal endogenous hormone production. Clinical trials have shown that the use of either ERT or HRT in both premenopausal and postmenopausal women increases the risk of cardiovascular events.[118-121] However, ERT or HRT do not cause drug-induced hypertension in postmenopausal women.[122]

Hormonal dysregulation can cause hypertension by inducing insulin resistance (the metabolic syndrome), sodium and water retention, or myriad other effects. Other miscellaneous agents cause hypertension via unique mechanisms not related to these neurohumoral effects. Both erythropoietin-α and darbepoetin-α can cause dose-dependent increases in blood pressure.[123] Possible mechanisms include increased hematocrit and erythrocyte mass, changes in the production or sensitivity of endogenous vasopressor and vasodilatory factors, alterations in vascular smooth muscle, direct vasoconstriction, and arterial remodeling by stimulation of vascular cell growth.[124] However, the exact mechanism is unknown.

REBOUND HYPERTENSION

The adrenergic antihypertensive agents, β-blockers and centrally acting α-receptor agonists, can cause rebound hypertension when therapy is abruptly discontinued.[8-27] Long-term exposure to β-blocking agents causes upregulation and increased expression of β-receptors. When β-blocker therapy is abruptly discontinued, excessive stimulation of these additional β-receptors occurs, potentially resulting in increases in blood pressure and heart rate, leading to rebound hypertension. Cardioselective β-blockers or those with intrinsic sympathomimetic activity have been touted as not being associated with rebound hypertension, but this has not been proven. The mechanism by which rebound hypertension occurs in association with central α-agonists has not been fully established, but is believed to be similar to that of β-blockers. When exposed to long-term central α-agonist therapy, α-receptor density, sensitivity, or both can increase.[5] Abrupt discontinuation of therapy with central α-agonists leads to elevated plasma norepinephrine concentrations, peripheral α-receptor stimulation, and increased blood pressure. This occurs in association with both oral and transdermal administration.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The classification of blood pressure is based on systolic and diastolic blood pressure values (Table 27-2).[2] This classification includes normal blood pressure, elevated blood pressure, stage 1 hypertension, and stage 2 hypertension. Elevated blood pressure and the development of hypertension are nearly always asymptomatic. Therefore, assessing patients for the presence of signs and symptoms of drug-induced hypertension (**Table 27-4**) is not very helpful. When blood pressure elevations are extreme (usually much higher than 200/110 mm Hg), symptoms consistent with hypertensive emergency (e.g., anxiety, chest pain, confusion, excessive perspiration, nausea/vomiting, pale or red skin, visual changes) are more likely to be present but are still not common.

Table 27-4 Signs and Symptoms Associated with Drug-Induced Hypertension

- No symptoms usually reported by patients
- Increase in blood pressure
- In patients with a history of treated hypertension, requirement for increased doses of antihypertensive medications
- In patients with a history of treated hypertension, need for additional antihypertensive agents to maintain blood pressure goal
- Rarely, hypertensive emergency: neurologic deficits, anxiety, nausea, vomiting, chest discomfort, back pain, dyspnea, visual changes

The clinical significance of elevated blood pressure associated with the use of a drug varies, depending on an individual's baseline blood pressure. Moreover, the precise time of onset for drug-induced hypertension is unknown and likely highly variable and dependent on the particular mechanism of drug-induced hypertension. For the purposes of this chapter, drug-induced hypertension will be defined as blood pressure increases from baseline that confer stage 1 hypertension or higher. The threshold blood pressure for the diagnosis of hypertension is 130/80 mm Hg.

Drug-induced blood pressure elevations, if persistent, may be clinically significant even if the blood pressure is not increased to above an individual's goal value. Many drugs have been reported to induce statistically significant blood pressure increases, some as small as 2–4 mm Hg.[6-108] The clinical significance of these small increases is debatable. However, data from observational studies and randomized trials suggest that a 2 mm Hg reduction in diastolic blood pressure correlates with a 17% decrease in the prevalence of hypertension, a 6% reduction in the risk of coronary heart disease (CHD), and a 15% reduction in the risk of stroke and transient ischemic attacks.[125-127] It has been documented that patients with blood pressure in the stage 1 hypertension range have a higher risk of cardiovascular events than patients with normal blood pressure (see Morbidity and Mortality section, below).[128] Therefore, depending on a patient's baseline blood pressure, small but persistent blood pressure increases may be clinically significant.

Several other conditions should be considered in patients with suspected drug-induced hypertension (**Table 27-5**). The possibility of new-onset primary (essential) hypertension must always be considered. The patient's blood pressure history and a comprehensive medical examination are necessary components for this evaluation. Other origins of secondary hypertension in addition to drug-induced causes should also be ruled out. Additional diagnostic tests such as laboratory evaluations, polysomnography, and aortic and kidney imaging may be required for a comprehensive evaluation.

Table 27-5 Conditions to Consider in the Differential Diagnosis of Drug-Induced Hypertension

Primary hypertension

- New onset
- Undiagnosed
- Previously diagnosed but not at goal blood pressure

Secondary hypertension

- Alcohol abuse
- Cancer
- Chronic kidney disease
- Coarctation of the aorta
- Cushing syndrome
- Hyperparathyroidism
- Pheochromocytoma
- Polycystic kidney disease
- Primary aldosteronism
- Renovascular disease
- Sleep apnea
- Thyroid disease

Table 27-6 Risk Factors for Drug-Induced Hypertension

- Elevated blood pressure in the past
- History of hypertension or elevated blood pressure
- Previous history of drug-induced hypertension
- Decreased glomerular filtration rate (especially <60 mL/min/1.73 m^2)
- Metabolic syndrome
- Advanced age
- Persistent use of high-dose NSAID therapy

NSAID = nonsteroidal anti-inflammatory drug.

RISK FACTORS

Patient-specific risk factors for drug-induced hypertension are listed in **Table 27-6**. Perhaps the most relevant is a history of increased blood pressure, either significant enough to fulfill the diagnostic criteria for hypertension or high enough to be classified as elevated blood pressure. A history of drug-induced hypertension or drug-induced increases in blood pressure is also noteworthy. There are many major cardiovascular risk factors that increase the risk of target organ damage associated with hypertension. One prospective cohort study evaluating oral contraceptive–induced hypertension showed that the relative risk for hypertension increased from 1.5 to 1.8 when other hypertension risk factors were considered.[66] Therefore, major cardiovascular risk factors should be considered when evaluating a patient's overall risk of drug-induced hypertension.

Age has been identified as a risk factor for several forms of cardiovascular disease.[5] NSAID-induced elevations in blood pressure are especially prominent in the elderly population.[78] Data from a case-control study of 9,411 elderly patients in whom antihypertensive therapy was initiated revealed that chronic NSAID users had a higher risk of initiating antihypertensive therapy than nonusers (OR 1.66, 95% CI 1.54–1.80).[80] A dose-dependent relationship with regard to risk was also revealed in this database. These findings suggest that age and dose, at least with persistent NSAID therapy, are both risk factors for drug-induced hypertension.

MORBIDITY AND MORTALITY

Morbidity and mortality, manifesting as cardiovascular disease, are clearly increased in patients with primary hypertension. However, the exact association between drug-induced hypertension and morbidity and mortality is unknown. A reasonable assumption is that prolonged drug-induced hypertension would result in a similar increase in risk of cardiovascular disease as compared with primary hypertension. Approximately 85 million Americans have some form of cardiovascular disease.[1] CHD is a long-term complication of hypertension that is the largest contributor to hypertension-related morbidity and mortality. It is often the fatal event related to cardiovascular mortality. Estimates have identified CHD as the most costly physical health condition in the United States.[129] Moreover, cardiovascular disease is the primary cause of death in the United States.[1]

Hypertension-related complications manifest as target organ damage. The various forms of target organ damage include heart disease (left ventricular hypertrophy, CHD [angina, myocardial infarction, acute coronary syndrome], heart failure), cerebrovascular disease (ischemic stroke, transient ischemic attacks), chronic kidney disease, peripheral arterial disease, and retinopathy. Observational data have established a direct correlation between blood pressure elevation and risk of target organ damage in patients of all ages with hypertension.[127,130] Randomized, double-blind, placebo-controlled clinical trials have also clearly demonstrated reduced morbidity and mortality associated with blood pressure reduction in patients with hypertension, even in the very elderly.[2,131-137] Therefore, persistent drug-induced hypertension may be associated with long-term increased risk of target organ damage.

A consistent, continuous, and independent relationship between blood pressure and risk of cardiovascular disease and other target organ damage is present in patients with elevated blood pressure that is not sufficiently high to be classified as hypertension.[2,128] Starting at a blood pressure of 115/75 mm Hg, the risk of future cardiovascular disease doubles with every 20 mm Hg increase in systolic blood pressure and 10 mm Hg increase in diastolic blood pressure.[130] Therefore, drug-induced increases in blood pressure, even within the normal or elevated blood pressure range, may be associated with a long-term increased risk of morbidity and mortality.

PREVENTION

Strategies for prevention of drug-induced hypertension are listed in **Table 27-7**. Drug-induced hypertension is ideally detected by closely monitoring blood pressure. Clinic-based blood pressure measurements should be obtained 2–4 weeks after initiating therapy with a drug known to increase blood pressure. Home or ambulatory blood pressure monitoring may be helpful but is not essential.[138-140] Moreover, both home and ambulatory blood pressure values are lower than those measured in the clinic. Average home blood pressure measurements are typically 5 mm Hg lower than clinic values, and 24-hour ambulatory blood pressure measurements in individuals with hypertension are typically 10 mm Hg lower.[140] However, clinic-based blood pressure measurements are sufficient for detecting drug-induced hypertension.

The most effective prevention strategy is avoiding the use of agents known to cause drug-induced hypertension. This is especially important in patients with either established cardiovascular disease or multiple risk factors for drug-induced hypertension or cardiovascular disease (Table 27-6). For women requiring oral contraceptive therapy, preparations with low estrogen (≤30 mcg ethinyl estradiol) and progestin (≤1 mg norethindrone) content appear to be associated with the lowest risk of hypertension.

Table 27-7 Approaches to Help Prevent Drug-Induced Hypertension

- Avoid use of agents reported to cause drug-induced hypertension in high-risk patients
- For patients taking medications known to cause drug-induced hypertension:
  - Avoid tyramine-containing foods in patients taking monoamine oxidase inhibitors
  - Use minimum effective dose of NSAIDs, including celecoxib
  - Measure blood pressure at least every 2–4 weeks
  - Evaluate for symptoms of hypertension-related target organ damage periodically
- Engage in lifestyle modifications:
  - Weight reduction: Maintain normal body weight and body-mass index, 18.5–24.9 kg/m^2
  - Adopt the DASH eating plan: consume a diet rich in fruits, vegetables and low-fat dairy products with a reduced content of saturated and total fat
  - Reduce dietary sodium intake to 1.5 g sodium daily
  - Engage in regular aerobic physical activity (at least 30 minutes/day, most days of the week)
  - Moderate alcohol consumption: limit consumption to ≤2 drinks/day in most men and ≤1 drink/day in women and lighter-weight persons

DASH = dietary approaches to stop hypertension, NSAID = nonsteroidal anti-inflammatory drug.

Lifestyle modifications that lower cardiovascular risk and blood pressure should be recommended for all patients, especially those using drugs known to increase blood pressure.[141,142] These modifications include diet and exercise recommendations. The Dietary Approaches to Stop Hypertension (DASH) diet is rich in vegetables, fruits, and low-fat dairy products and has been proven to lower blood pressure.[142] Other methods, such as weight reduction, dietary sodium restriction, moderate and regular aerobic activity, and moderation of alcohol consumption are also effective in lowering blood pressure.

MANAGEMENT

Management of drug-induced hypertension depends on differentiating drug-induced from either primary or other secondary causes of hypertension. When drug-induced hypertension is strongly suspected, the offending agent should be discontinued when possible (**Table 27-8**). Blood pressure should then return to baseline values within 2–4 weeks under most circumstances. If the blood pressure remains consistently elevated after discontinuing therapy with the offending agent, further investigation to evaluate primary hypertension or other secondary causes is needed. The offending agent should not be reintroduced. However, if no reasonable treatment alternative can be identified, a reintroduction of therapy with a reduced dose and blood pressure monitoring may be attempted. Lifestyle modifications to lower blood pressure, as previously discussed, should be implemented in these patients.

CALCINEURIN INHIBITORS

When therapy with certain offending agents must be continued, specific management approaches may be considered (Table 27-8). Cyclosporine and tacrolimus, which are calcineurin inhibitors, are immunosuppressant agents that are used in patients after solid organ transplantation and to treat a variety of other conditions.[51-53,102] Due to their crucial role in therapy, calcineurin inhibitors usually cannot be discontinued. Therefore, managing the drug-induced hypertension is the primary goal in these patients.

Table 27-8 Management of Drug-Induced Hypertension

Drug	Management
Most agents	Discontinue offending agent when possible
Cyclosporine	• If stage 1 hypertension, decrease dose by 25% • If stage 2 hypertension, decrease dose by 50%, and consider antihypertensive therapy • Dihydropyridine calcium channel blockers are preferred antihypertensive agents
Erythropoietin and darbepoetin	• Use the lowest effective dose: decrease dose if hemoglobin concentration approaches 12 g/dL or if hemoglobin increase is >1 g/dL in a 2-week period; hold dose if hemoglobin concentration exceeds 13 g/dL • Subcutaneous administration is preferred over intravenous to minimize abrupt increases in blood pressure
Oral contraceptives	

	- Monitor blood pressure for up to 3 months after discontinuation of therapy - When no other form of contraception is feasible, use the lowest estrogen/progestin-content product and treat with antihypertensive therapy
Rebound hypertension from discontinuation of therapy with β-blockers or central α-agonists	- Reinitiate therapy with agent at previous long-term dose - Gradually taper if therapy is to be discontinued

A consensus guideline based on reports from clinical trials and from clinical experience using cyclosporine in patients with rheumatoid arthritis was published in 1999.[143] When patients taking cyclosporine have stage 1 hypertension on at least two consecutive visits, the cyclosporine dose should be reduced by 25%. The dose should be reduced by 50% in those in whom stage 2 hypertension develops, and initiation of antihypertensive pharmacotherapy may be necessary. If blood pressure remains elevated despite initial dose reductions, additional reductions and initiation of antihypertensive pharmacotherapy should be considered. Persistent blood pressure elevation may require cyclosporine discontinuation if an acceptable alternative agent can be used.

Dihydropyridine calcium-channel blockers (e.g., amlodipine, felodipine) are preferred agents for the treatment of cyclosporine-induced hypertension.[117,143] These agents do not interact with cyclosporine and promote vasodilation of the afferent and efferent renal arterioles. Pharmacologically, this mechanism of action is ideal for managing cyclosporine-induced hypertension. Nondihydropyridine calcium-channel blockers (i.e., diltiazem, verapamil) increase serum cyclosporine concentrations and are less desirable pharmacotherapy options for cyclosporine-induced hypertension. Patients with pre-existing hypertension treated with a β-blocker can remain on this therapy. However, diuretics, angiotensin-converting enzyme inhibitors, or angiotensin-II receptor blockers are not highly effective for managing this type of hypertension, and their use as first-line agents for cyclosporine-induced hypertension is discouraged.[116,143]

Guidelines for management of tacrolimus-induced hypertension have not been published. An approach similar to that recommended for cyclosporine-induced hypertension is reasonable. However, manufacturers' recommendations are to control blood pressure "with any of the common" antihypertensive agents.[102] These recommendations state that because tacrolimus may cause hyperkalemia, potassium-sparing diuretics should be avoided. As with cyclosporine, certain calcium-channel blockers (diltiazem, verapamil) can increase serum tacrolimus concentrations and should be avoided or used with extreme caution.

ORAL CONTRACEPTIVES

Women who are treated with estrogen-containing oral contraceptive agents should have their blood pressure measured within the first month of treatment, then after 3, 6, and 12 months. If oral contraceptive-induced hypertension occurs, the drug should be discontinued and replaced with an alternative form of contraception. Blood pressure should return to pretreatment values within 3 months after discontinuation of therapy. If it does not, additional evaluation for primary hypertension or other secondary forms of hypertension is necessary. If an alternative form of contraception cannot be used and other secondary forms of hypertension are ruled out, an oral contraceptive agent with a low estrogen (≤30 mcg ethinyl estradiol) and progestin (≤1 mg norethindrone) content may be used. Lifestyle modifications should be implemented, with the addition of antihypertensive drug therapy when necessary.

According to the American College of Obstetricians and Gynecologists, women with pre-existing and well-controlled hypertension who are younger than 35 years of age may initiate a trial of combined oral contraceptives if the woman is otherwise healthy, exhibits no evidence of end-organ vascular disease, and does not smoke cigarettes. Careful monitoring should be performed for several months following initiation of the combined oral contraceptive.[144] If blood pressure remains controlled, therapy may be continued. If hypertension occurs, progestin-only or nonhormonal contraceptives should be used as an alternative method.

ERYTHROPOIESIS-STIMULATING AGENTS

Erythropoietin-α and darbepoetin-α are erythropoiesis-stimulating agents that are indicated for the treatment of anemia associated with chronic kidney disease, human immunodeficiency virus infection and cancer chemotherapy, and for reduction of the need for allogeneic blood transfusion in surgery.[57,63,64] These drugs can enhance quality of life and improve cardiac function. Discontinuing therapy is not always a feasible option to manage hypertension induced by these drugs. Although lifestyle modifications might minimize blood pressure increases, close monitoring of serum hemoglobin concentration during therapy is essential to avoid excessive therapeutic effects that can result in blood pressure elevations. The dose of these agents should be reduced if serum hemoglobin concentrations approach 12 g/dL or if increases in serum hemoglobin concentration exceed 1 g/dL in a 2-week period. Therapy should be withheld if serum hemoglobin concentrations exceed 13 g/dL.[57,63,64]

Use of erythropoiesis-stimulating agents in patients with chronic kidney disease undergoing dialysis treatment requires close monitoring for the development of drug-induced hypertension. The need for dialysis alone increases the risk of hypertension or worsening of hypertension. Optimizing dialysis treatments in patients with kidney disease, closely monitoring and managing volume status when needed, and using subcutaneous administration to ensure gradual red blood cell increases are additional strategies that may minimize the risk of blood pressure elevations.[145]

REBOUND HYPERTENSION

When rebound hypertension occurs after abrupt discontinuation of a β-blocker or a centrally acting α-receptor agonist, therapy with the drug should be reinitiated at the previous long-term dose. If discontinuation of therapy with the offending agent is intended, therapy can be reinitiated, with the dose subsequently gradually decreased, followed by discontinuation. There are no guidelines regarding the optimal manner in which to gradually discontinue therapy with such medications. However, the dosing schedule should be individualized based on the dose of the drug that caused the rebound hypertension. A 50% dose decrease for 3–7 days is considered a tapering step. If a patient experiences rebound hypertension on a low-to-moderate dose of a drug, one tapering step may be sufficient to treat rebound hypertension, whereas two or more tapering steps may be needed for patients receiving higher doses.

INFORMATION FOR PATIENTS

Patients taking drugs that are known to cause drug-induced hypertension should be made aware of the potential risks. Patients should be counseled that their blood pressure may increase to the point of a diagnosis of hypertension. They should be instructed to comply with medical visits to detect elevations in blood pressure. Patients should also be encouraged to periodically monitor and document their blood pressure values outside of their prescribing practitioner’s office (e.g., at home, in a community pharmacy). If persistent increases in systolic or diastolic blood pressure values are detected (even if small) or blood pressure increases to above their goal value (Table 27-2), patients should consult a healthcare professional (e.g., pharmacist, physician). If symptoms consistent with hypertensive emergency develop (e.g., chest pain, unilateral weakness, severe headache, shortness of breath), patients should be instructed to seek immediate emergency care.

Lifestyle modifications (Table 27-7) should be encouraged in all patients at risk for hypertension, especially those receiving drugs that may cause hypertension. Patients using β-blockers or centrally acting α-receptor agonists should be educated regarding potential rebound hypertension and instructed not to abruptly discontinue therapy with these agents. Use of any nonprescription medication without first consulting a pharmacist or other healthcare professional should be discouraged. Lastly, patients should be encouraged to ensure that all healthcare professionals involved with providing their care are fully aware of all current medications and risk factors for hypertension so that new medications that may potentially interact with drugs or further increase the risk of hypertension can be avoided.

CHAPTER 28

Hypotension

Katy E. Trinkley and Robert L. Page II

Drug-induced hypotension is a clinically important and potentially disabling problem, which can lead to syncope, falls and injury, or sustained lack of organ perfusion resulting in ischemia, infarction, or both. These hypotension-related complications can be the result of either chronic hypotension, acute hypotension in the institutionalized setting, or orthostatic hypotension. Chronic hypotension describes the situation when the blood pressure is consistently low, regardless of posture, whereas orthostatic hypotension describes a decline in blood pressure upon assuming an upright position. The majority of drug-induced hypotension episodes are the result of orthostatic hypotension, also referred to as postural hypotension. Orthostatic hypotension is a reduction in systolic blood pressure of at least 20 mm Hg or a reduction in diastolic pressure of at least 10 mm Hg within 3 minutes of standing or during a head-up tilt test of at least 60 degrees.[1-4]

Drug-induced orthostatic hypotension is primarily due to autonomic failure in which the causative agent affects central or peripheral autonomic pathways.[5] However, orthostatic hypotension can also result from neurally mediated syncope.[5] Autonomic failure involves chronic debilitation of sympathetic efferent activity such that vasoconstriction is impeded. Upon standing, blood pressure precipitously falls and presyncope or syncope develops. In neurally mediated orthostatic hypotension, the typical pattern of autonomic outflow that preserves blood pressure in the standing position is acutely reversed in response to a trigger.

CAUSATIVE AGENTS

Drugs that cause hypotension can be separated into two groups: those for which hypotension is an extension of the drug's therapeutic effect (e.g., antihypertensives) and those for which hypotension is not an extension of the drug's therapeutic effect. Examples of drugs that may cause orthostatic hypotension include phenothiazines, tricyclic antidepressants, anxiolytics, and levodopa/carbidopa. **Table 28-1** lists drugs that have been reported to cause hypotension and their respective incidences.[6-248]

EPIDEMIOLOGY

Drug-induced chronic hypotension is less common than drug-induced orthostatic hypotension, because causes of drug-induced chronic hypotension, such as over-intensive antihypertensive therapy, are generally more easily correctable. As a result, the prevalence of drug-induced chronic hypotension is unknown. Orthostatic hypotension from all causes has been estimated to occur in 0.5% of individuals in the general population, with older adults and acutely ill patients at greater risk. Approximately 5% of individuals under 50 years of age experience orthostatic hypotension, which increases to a prevalence of 30% in individuals over 70 years of age.[3] In acute care settings, 17% of patients experience orthostatic hypotension,[5] while the prevalence of orthostatic hypotension among patients presenting with syncope to the emergency department ranges from 21–64%.[249,250]

Table 28-1 Agents Implicated in Drug-Induced Hypotension

Drug	Incidence	Level of Evidence[a]
ANTIHYPERTENSIVES		
ACE INHIBITORS[b,c,d]		
Benazepril[6]	0.3–0.4%	A
Captopril[7,8]	3.6%	A
Enalapril (particularly with IV administration)[9]	0.9–6.7%	A
Fosinopril[10]	2.4–4.4%	A
Lisinopril[11]	Up to 11%	A

Moexipril[12]	0.5%	A
Perindopril[13]	0.3–0.8%	A
Ramipril[14]	2–11%	A
Quinapril[15]	2.9%	A
Trandolapril[16]	0.6–11%	A
ANGIOTENSIN-RECEPTOR BLOCKERS[b,c,d]		
Azilsartan[17]	0.4%	A
Candesartan[18]	18.8%	A
Eprosartan[19]	<1%	A
Irbesartan[20]	0.1–5.4%	A
Losartan[21,22]	0.5–7%	A
Olmesartan[23]	0.1%	A
Telmisartan[19]	<1%	B
Valsartan[24,25]	6.9%	A
PERIPHERAL α-BLOCKERS[c,d]		
Alfuzosin[26]	0.4–2%	A
Doxazosin[27,28]	0.3–10%	A
Prazosin[29,30]	1–4%	A
Tamsulosin[31]	0.2–0.4%	A
TERAZOSIN[32,33]	1.3–7%	A
β-ADRENERGIC BLOCKERS (PARTICULARLY WITH IV ADMINISTRATION)		
Acebutolol[34,35]	2%	B
Atenolol[36,c]	4–25%	A
Betaxolol[37,c]	<2%	A
Bisoprolol[38]	Up to 12%	A
Carvedilol (particularly immediate-release)[39,b]	2–20%	A
Esmolol[40,41]	20–50%	A
Propranolol[42,43]	NK	A
Labetalol[44,45]	Oral 1%, IV 5%	A
Metoprolol (particularly immediate-release)[46,b]	27.4%	A
Nadolol[47]	1%	A

Pindolol[48,49]	2%	A
Nebivolol[50]	0.5%	A
CALCIUM-CHANNEL BLOCKERS		
Amlodipine[51,c]	<1%	A
Diltiazem (particularly with IV administration)[52,53]	6–11%	A
Felodipine[54]	0.5–1.5%	A
Isradipine[55]	NK	C
Nicardipine (particularly with IV administration)[56]	0.9–5.6%	A
Nifedipine (particularly immediate-release)[57]	0.5–5%	A
Nimodipine[58,59]	Up to 8.1%	A
Nisoldipine[60]	<1%	A
Verapamil (particularly with IV administration)[61,62]	1–3%	B
CENTRALLY ACTING α-ADRENERGIC AGONISTS[c]		
Clonidine (lowest with patch, highest with IV administration)[63]	Up to 44.8%	A
Guanfacine[64,65]	15%	A
Guanabenz[66,67]	<1%	A
Methyldopa[68]	NK	B
Reserpine[69,70]	16%	A
PERIPHERAL-ACTING ARTERIAL VASODILATORS		
Diazoxide[71,72]	NK	B
Hydralazine (particularly with IV administration)[71-76]	NK	B
Minoxidil[77,78]	NK	B
Nitroglycerin[406-408]	4%	A
Nitroprusside[79]	NK	B
DIURETICS[b,c]		
Amiloride[80,81]	<1%	B
Bumetanide[82]	0.8%	A
Chlorothiazide[83]	NK	B
Chlorthalidone[84]	2.2%	A

Ethacrynic acid[85]	NK	B
Furosemide[86,87]	20%	A
Hydrochlorothiazide[87,88]	12.5–60%	A
Indapamide[89]	<5%	A
Metolazone[90,91]	NK	B
Torsemide[92,93]	0–7%	A
DOPAMINE AGONISTS		
Fenoldopam[94,95,c,e]	2–18.5%	A
RENIN INHIBITORS		
Aliskiren[96]	0.1%	A
NONANTIHYPERTENSIVES		
ANGIOTENSIN-RECEPTOR NEPRILYSIN INHIBITOR		
Sacubitril/Valsartan[409]	18%	A
ALZHEIMER DISEASE AGENTS		
Galantamine[97,98,c,d]	1–3.6%	A
Donepezil[99,100,c,d]	1–3%	A
ANESTHETIC AGENTS		
Bupivacaine[101,102,c]	NK	B
Halothane[103,104,c]	NK	B
Isoflurane[105,106,c]	NK	B
Propofol[107,108,c]	3–10%	A
ANTIANGINAL AGENTS		
Amyl nitrate[109,110]	NK	C
Isosorbide dinitrate[111,112]	16%	A
Isosorbide mononitrate[113]	<5%	A
Nitroglycerin[114,115,c,d]	1–48%	A
ANTIARRHYTHMIC AGENTS		
Amiodarone (IV only)[116,117]	10–20%	A
Bretylium[118,119,e]	50%	A
Ibutilide[120,121]	2%	A
Mexiletine[122,f]	<1%	C
Procainamide (IV only)[123,124]	NK	C
Quinidine[125,126,d,e,f]	NK	C

Sotalol[127,128]	5–9%	A
Tocainide[129]	3%	A
Vernakalant[130,131,e]	5–6%	A
ANTIDIABETIC AGENTS		
Dapagliflozin[410]	0.6–0.8%	A
ANTIDEPRESSANTS		
Amitriptyline[132,133,c,f]	5–20%	A
Clomipramine[134,c,f]	4–6%	B
Doxepin[135,136,c]	3–4%	B
Desipramine[133,137-139,c,f]	Up to 15%	A
Imipramine[133,139-144,c,f]	20–37%	A
Trazodone[145,c]	3.8–7%	B
ANTIEMETICS		
Droperidol[146,d]	NK	B
Prochlorperazine[147,148,d]	1.2%	B
Promethazine[149,e]	NK	B
ANTIEPILEPTIC DRUGS		
Phenytoin (IV only)[150,151]	4.9%	A
Fosphenytoin (IV only)[152,d,e]	7.7%	A
ANTIHISTAMINIC AGENTS		
Diphenhydramine[153,f]	NK	C
ANTIMICROBIAL AGENTS		
Pentamidine (IV and IM only)[154,155]	1.7–5%	B
Levofloxacin (IV only)[156,e]	NK	C
Vancomycin (IV only)[157,158,e]	0–63%	A
ANTIPARKINSONIAN AGENTS		
Bromocriptine[159,160,c,d]	0.2–0.7%	A
Carbidopa plus levodopa[161,162,c,d]	1%	A
Pergolide[163,c]	2.1%	A
Pramipexole[164,165,c]	<5%	A
Ropinirole[166,167,c]	2–25%	A
Selegiline[168,c]	9.8%	A
	7–44%	A

Rasagiline169,c		
Entacapone170,c	1.2%	A
Tolcapone171,c	13–14%	A
ANTIPSYCHOTIC AGENTS		
Aripiprazole172,173,c	0.2–4%	A
Aripiprazole lauroxil411	0.2–0.5%	A
Brexpiprazole412	0.1–0.4%	A
Chlorpromazine (particularly IV)413,c	0–10%	A
Clozapine174,175,c,d	9–13%	A
Haloperidol176,177,c	0–2%	A
Loxapine178,179,c,d	0.4–3%	A
Lurasidone180	0.3–2.1%	A
Olanzapine181,c	2%	A
Quetiapine182,183,c	Up to 7%	A
Pimozide184-186,c	NK	C
Risperidone187-189,c	Oral 1–2%, IM: <4%	A
Thioridazine190,191,c	16%	A
Thiothixene178,192	4%	A
Trifluoperazine176	NK	C
ZIPRASIDONE176,193,194,C,D	1.3–18%	A
β-ADRENERGIC AGONISTS		
High-dose dobutamine195-197,d	20%	A
BIOLOGIC AGENTS		
Interleukin-2198,d	71%	A
Muromonab-CD3199,200	25%	A
Defibrotide414	37%	A
CHEMOPROTECTANT AGENTS		
Amifostine201-203,d,e	3–62%	A
CANCER CHEMOTHERAPY AGENTS		
Cabozantinib415	7%	A
Carmustine204,205,d	NK	B
Dinutuximab416	60%	A

Tadalafil[242]	2%	A
PROSTAGLANDINS		
Epoprostenol[243-245,d,e]	13–16%	A
Iloprost[246-248]	11–76%	A

SOLUBLE GUANYLATE CYCLASE STIMULATORS		
Riociguat[417]	10%	A

ACE = angiotensin-converting enzyme, IM = intramuscular, IV = intravenous, NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials;

Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Higher incidence in patients with heart failure.

[c] May also cause orthostatic hypotension.

[d] Dose-related.

[e] Administration rate-related.

[f] In overdose.

MECHANISMS

Mean arterial pressure is determined by heart rate, stroke volume, and total peripheral resistance. When a person changes from a supine to an upright position, orthostatic hypotension results from a profound and immediate shift of blood volume primarily to the lower extremities. Within 10–15 minutes of a posture change, stroke volume may decline by 15%, and roughly 1 L of blood may pool in capacitance vessels below the diaphragm.[251,252] The resultant reduction in venous return and decreases in cardiac output and blood pressure stimulate arterial baroreceptors, which trigger intricate compensatory mechanisms. Centrally mediated activation of sympathetic efferent neurons increases vascular tone, myocardial contractility, and heart rate. Cardiopulmonary volume receptors cause vasopressin release, which also leads to arteriolar vasoconstriction and water conservation by the kidney. All of these reflex mechanisms limit the potentially adverse hemodynamic effects of an upright posture; however, should any one or a combination of these mechanisms fail, orthostatic hypotension may result.[253]

Orthostatic hypotension can be the direct result of chronic autonomic failure from neurodegenerative conditions such as Parkinson disease, or it can be secondary to conditions such as diabetes, which is associated with higher-risk neurological conditions.[3] Conditions or situations that impair diastolic filling such as blood loss, dehydration, and excessive diuresis may also lead to orthostatic hypotension. One example is splanchnic blood pooling that occurs after eating, which can lead to a decrease in blood pressure.[254]

In healthy patients of any age, orthostatic hypotension occurs infrequently. However, as patients age, changes in cardiovascular physiology, concomitant diseases, and exposure to medications that may reduce blood pressure increase the risk of orthostatic hypotension. Physiologic changes that may contribute to orthostatic hypotension include alterations in baroreceptor activity, parasympathetic activity, arterial and cardiac compliance, renal sodium conservation, vasopressin response, plasma renin activity, plasma angiotensin and aldosterone concentrations, and plasma volume.[255]

The administration of drugs that interfere with the cardiovascular reflex response can unmask or exacerbate orthostatic hypotension. For example, antihypertensive agents may produce hypotension by decreasing sympathetic outflow through central and peripheral vasodilatory actions or by depleting intravascular volume. There are many drugs that cause direct vasodilation resulting in drug-induced hypotension. Drugs can induce hypotension through many different mechanisms (**Table 28-2**).[5,34,36-40,43,49-51,69,70,74-78,94,98,109,110,114-117,124,150-153,195-197,212-214,219-221,232,233, 235,236,243,246-248,256-296]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Orthostatic hypotension may manifest with symptoms as mild as light-headedness or as severe as presyncope or syncope (**Table 28-3**).[3,253,297,298] Although presyncope is less severe than syncope, it may be a part of a continuum that leads to syncope, which is a sudden loss of consciousness and postural tone usually lasting no more than 15 seconds.[297] The “common faint,” or neurocardiogenic syncope (also called vasovagal syncope), is most common, in which the triggering of a neural reflex results in a usually self-limited episode of systemic hypotension characterized by both bradycardia and peripheral vasodilation.[250,253] If syncope occurs as a result of neurocardiogenic syncope, hypoperfusion-related symptoms typically resolve immediately when supine.[298] The syncope associated with orthostatic hypotension is generally differentiated from other causes such as seizures by a lack of postictal confusion or drowsiness. Symptoms of syncope are most commonly documented in the morning, after medication administration or following meals. Focal neurologic findings, if present, may suggest concomitant cerebrovascular disease.[277] Although there is not a clear rationale for each, common signs and symptoms associated with orthostatic hypotension include mild anemia, hypohidrosis, a Parkinsonian-like syndrome, recurrent urinary tract infection, bladder dysfunction, sleep apnea, hoarseness, nasal stuffiness, impotence, constipation, or diarrhea.[253] Anemia is believed to be due to decreased erythropoietin release related to reduced β_2 adrenoceptor stimulation, while bladder dysfunction or urinary tract infections may lead to dehydration and ultimately orthostatic hypotension, which could also be related to an underlying neurogenic condition.[299]

Table 28-2 Mechanisms of Drug-Induced Hypotension

Drug	Mechanism
Benazepril Captopril Enalapril Fosinopril Lisinopril Moexipril Perindopril Ramipril Quinapril Trandolapril	Inhibition of angiotensin II with increase in bradykinin concentrations[256]
Aliskiren	Inhibition of renin[256]
Candesartan Eprosartan Irbesartan Losartan Olmesartan Telmisartan Valsartan	Inhibition of angiotensin II at the receptor level[257]
Acebutolol Atenolol Betaxolol Bisoprolol Esmolol Propranolol Metoprolol Nadolol Pindolol Nebivolol	Blockade of β-adrenoreceptors[34,36-38,40,43,49,50]
Carvedilol Labetalol	Blockade of β- and α_1-adrenoreceptors[39,258]
Amiloride Bumetanide Chlorothiazide Chlorthalidone Ethacrynate Furosemide Hydrochlorothiazide Indapamide Metolazone Torsemide	Inhibition of renal sodium reabsorption thereby leading to intravascular volume depletion[259-261]
Mannitol	Intravascular volume depletion[235,236]
Atracurium Codeine d-tubocurare Hydromorphone Fentanyl Mivacurium	Release of histamine[221,232,233,262-265]

Morphine Succinylcholine Vancomycin	
Alfuzosin Aripiprazole Chlorpromazine Clozapine Doxazosin Haloperidol Loxapine Lurasidone Olanzapine Pimozide Prazosin Quetiapine Risperidone Tamsulosin Terazosin Thioridazine Thiothixene Trifluoperazine Ziprasidone	Blockade of central and/or peripheral[5,266,267] α-adrenoreceptors[5,266,267]
Dobutamine, high-dose	The following mechanisms may be responsible[195-197]: • Inadequate increase in cardiac output due to impaired systolic reserve • Marked prolongation of isovolumic relaxation time due to induced myocardial ischemia • Marked isolated reduction in systemic vascular resistance • Decrease in cardiac output associated with cavity obliteration and reflex bradycardia
Clonidine Guanfacine Guanabenz Methyldopa	Direct stimulation of α-receptors in the vasomotor center of the medulla leading to[268]: • Reduction in peripheral vascular resistance • Decreased heart rate (secondary to increased vagal tone)
Reserpine	Depletion of catecholamine and 5-hydroxytryptophan in the central nervous system resulting in[69,70]: • Decreased peripheral resistance • Reduced cardiac output
Chlorpromazine Prochlorperazine Promethazine	• Calmodulin-mediated inhibition of phosphodiesterase • Relaxation of vascular smooth muscle[5]
Amitriptyline Clomipramine Desipramine Doxepin Imipramine Trazodone	Reduced systemic vascular resistance due to α-adrenoreceptor blockade[269,270]
Amlodipine Diltiazem Felodipine Isradipine	Blockade of L-type calcium channel[51,271]

Nicardipine Nifedipine Nimodipine Nisoldipine Verapamil	
Pentamidine, intravenous	Vasomotor reaction[153]
Interleukin-2	Increased capillary permeability; decreased peripheral vascular resistance[273]
Amifostine Diazoxide Epoprostenol Hydralazine Iloprost Minoxidil	Direct arteriolar vasodilation[74-78,243,246-248,274,275]
Nitroprusside	Director arteriolar and venous vasodilation[79]
Bosentan Treprostinil	Inhibition of endothelin-1[214,276,277]
Milrinone	Inhibition of phosphodiesterase type III[278,279]
Nesiritide	Stimulates guanylate cyclase-linked natriuretic peptide A/B receptors[220]
Diphenhydramine	Inhibition of fast sodium channels Inhibition of potassium channels in overdose[280]
Dacarbazine	Calcium chelation by citric acid in the preparation[281]
Carmustine	Vasodilation due to alcohol content of the diluent[282,283]
Vincristine	Neurotoxicity Inhibition of norepinephrine secretion[212,213]
Vinblastine	Neurotoxicity[211]
Magnesium	Opposition of calcium-dependent arterial constriction[284] Improves endothelial function
Amiodarone Etoposide	Vasoactive solvents in the intravenous formulation[117,285]
Amyl nitrate Isosorbide dinitrate Isosorbide mononitrate Nitroglycerin	Increase intracellular cyclic guanosine monophosphate concentrations[109,110,114-116,219,286-288]
Procainamide, intravenous	Ganglionic blockade Central nervous system sympathetic inhibition[124]
Vardenafil Sildenafil Tadalafil	Inhibition of vascular phosphodiesterase type V[289]
Phenytoin Fosphenytoin	Vasodilation from the propylene glycol content (phenytoin only); unknown for fosphenytoin[150-152,290,291]
Bromocriptine Carbidopa–levodopa Entacapone	Increased dopamine, which exerts hypotension through the following:[292-295] Systemic, mesenteric, and renal vasodilation mediated by dopamine receptors

Pergolide Pramipexole Rasagiline Ropinirole Selegiline Tolcapone	Displacement of norepinephrine from nerve terminals Decreased renin and aldosterone secretion Reduction in sympathetic outflow
Fenoldopam	Systemic, mesenteric, and renal vasodilation mediated by dopamine receptor activation[94]
Donepezil Galantamine	Overactivation of muscarinic and nicotinic sites of autonomic and somatic nerves[98]
Propofol[180]	Direct vasodilation of venous smooth muscle[296]
Fludarabine Levofloxacin	Unknown

Table 28-3 Signs and Symptoms Associated with Drug-Induced Hypotension[3,253,297,298]

Most common

- Decline in systolic blood pressure ≥20 mm Hg or diastolic blood pressure ≥10 mm Hg within 1–3 minutes of standing, or during head-up tilt test of ≥60 degrees
- Lightheadedness
- Presyncope
- Syncope
- Blurry vision
- Weakness
- Buckling of legs
- Cognitive slowing
- Headache
- Neck pain
- Chest pain (in patients with underlying coronary artery disease)
- Seizure or clonic jerks (due to cerebral hypoxia)
- Dizziness
- Tachycardia
- Postprandial angina pectoris

Given that only 2% of elderly patients with orthostatic hypotension are symptomatic, proactive screening is important to identify those who may remain undiagnosed, in view of the fact that orthostatic hypotension increases morbidity and mortality.[3,300] A detailed medication history, including a review of prescription and nonprescription medications and supplements, a medical history, a thorough physical exam, and in some cases, specific diagnostic tests should be used to rule out other possible causes of hypotension. Conditions to consider in the differential diagnosis of drug-induced hypotension are presented in **Table 28-4**.[3,254,255,280,297,298]

To evaluate a patient for possible orthostatic hypotension, blood pressure and heart rate should be measured at three different times: after the patient has rested in the supine position for 5 minutes, immediately after the patient stands, and 1–2 minutes after standing. If the heart rate does not increase in the presence of orthostatic hypotension, then baroreceptor reflex dysfunction may be implicated. Heart rate responses to deep breathing and to the Valsalva maneuver may also aid in differentiating between autonomic impairment and other causes of orthostatic hypotension. As the time of day, ingestion of medications, and food consumption can influence orthostatic hypotension, the use of an ambulatory blood pressure monitor and a patient's corresponding log or diary of events may be necessary. Early morning measurements, especially after a high-carbohydrate meal, are helpful to identify symptoms from postprandial hypotension that may be contributing to drug-induced orthostatic hypotension. In the absence of an ambulatory blood pressure monitor, patients should be instructed to keep a detailed log with times and measurements of their blood pressure before breakfast, after taking their medications, after meals, and before bedtime.[255]

RISK FACTORS

Risk factors for drug-induced hypotension are presented in **Table 28-5**.[255] As mentioned previously, elderly patients are at increased risk for drug-induced orthostatic hypotension. The risk of orthostatic hypotension associated with some drugs may increase based on specific patient and drug characteristics. Patients at highest risk of amifostine-induced hypotension are those who receive doses in excess of 910 mg/m^2; have infusion times of 15 minutes or longer; have head and neck, esophageal, or lung cancer; have undergone neck irradiation; or have carotid artery disease or hypercalcemia.[201,218,301] Hypotension associated with intravenous opiates occurs primarily in hypovolemic patients; therefore, these agents should be avoided in patients with shock or reduced blood volumes. The risk of sildenafil-induced hypotension is greater in patients with spinal cord injuries, specifically cervical-level injuries.[302] Spinal cord injuries have not been established as a risk factor for hypotension with other phosphodiesterase type-5 inhibitors. Concurrent use of any phosphodiesterase type-5 inhibitor and nitrates should be avoided to prevent hypotension.[238,240,242,303] The frequency of orthostatic hypotension caused by tricyclic antidepressants and antipsychotic agents increases in patients with advancing age and those with overt cardiovascular disease, particularly in those with left ventricular dysfunction or autonomic disease.[5,304,305]

Table 28-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Hypotension[3,254,255,280,297,298]

Autonomic neuropathies

- Primary
    - Bradbury–Eggleston syndrome
    - Shy–Drager syndrome
    - Riley–Day syndrome
    - Dopamine–β-hydroxylase deficiency
    - Parkinson disease
    - Lewy body dementia
    - Idiopathic
- Secondary
    - Diabetes mellitus
    - Uremia
    - Guillain–Barré syndrome
    - Amyloidosis
    - Porphyria
    - Kidney disease
    - β_1-receptor polymorphisms
    - Spinal cord injury

Endocrine disorders

- Pheochromocytoma
- Hypoaldosteronism
- Renal vascular hypertension

Hypovolemic disorders

- Anemia
- Decreased plasma volume
- Hemorrhage
- Anorexia nervosa
- Diarrhea
- Overdialysis
- Overdiuresis

Transient neurogenic syncope

- Micturition syncope
- Carotid sinus syncope
- Vasovagal syncope
- Bezold–Jarisch reflex activation
- Glossopharyngeal neuralgia

Vascular insufficiency/vasodilation

- Varicose veins
- Arteriovenous malformations
- Absent venous valves
- Carcinoid syndrome
- Cardiogenic shock
- Mastocytosis
- Hyperbradykininism

Miscellaneous

- Anaphylaxis

- Nutritional deficiencies (vitamin B_{12}, folate)
- Pregnancy
- Space flight

Table 28-5 Risk Factors for Drug-Induced Hypotension[255]

- Alcohol use
- Cardiovascular disease
- Concurrent use of more than one drug associated with hypotension
- Decreased hepatic drug metabolism
- Fever
- Hot baths/showers
- Hot weather
- Hyperventilation
- Hyponatremia, hypokalemia
- Intravascular volume depletion
- Isometric exercise
- Large meals
- Overdiuresis
- Poor hepatic blood flow
- Prolonged recumbency
- Rapid ascent to high altitude
- Standing still
- Straining to urinate or defecate
- β_1-receptor polymorphisms

Patients receiving angiotensin-converting enzyme (ACE) inhibitors are at risk for hypotension if they are receiving high doses of diuretics, have a low serum sodium concentration (<130 mEq/L), have a serum creatinine concentration >1.7 mg/dL or have cardiovascular disease.[11,256,306] Hypotension associated with β-adrenergic-receptor blocking agents is more likely in patients with pretreatment systolic blood pressure <90 mm Hg, heart rate <60 beats/min, depressed left ventricular ejection fraction, or changes in fluid status.[307,308] The risk of hypotension associated with diuretics is increased in patients with generalized disability, dehydration, intravascular volume depletion, or concomitant use of vasodilating agents such as nitrates, alcohol, barbiturates, or narcotics.[309]

Genomic factors may also play a role in the development of orthostatic hypotension. Although results are conflicting, a single-nucleotide polymorphism with a glycine to arginine switch at position 389 of the β_1-adrenergic receptor has been found to significantly lower contractile responsiveness to catecholamines, thus increasing susceptibility to orthostatic hypotension.[280,310-312]

MORBIDITY AND MORTALITY

Drug-induced orthostatic hypotension may lead to falls, myocardial infarction, transient ischemic attack, stroke, and organ damage and may be particularly hazardous in the elderly population. Othostatic hypotension results in increased healthcare utilization, with an estimated 233 persons per 100,000 hospitalized for orthostatic hypotension and an average length of stay of 3 days.[313] Fifty percent of admissions due to an injury from a fall result in a discharge to a nursing home.[314] Of those admitted for orthostatic hypotension, nearly 1% die while hospitalized. Orthostatic hypotension is associated with an increased risk of mortality and cardiovascular morbidity and is an independent predictor of mortality and falls in the elderly. In community-dwelling elderly who sustain a fall, 5–10% suffer a serious injury such as a fracture, head trauma, or serious laceration.[315-318] These injuries can lead to considerable long-term mortality. In the older population, 1% of falls result in a hip fracture; within 1 year, these fractures are associated with a mortality rate of 20–30%.[314,319-321] The most severe consequences of drug-induced orthostatic hypotension are cerebrovascular accident, myocardial infarction, and death.[322-325] It is unknown whether death is directly owing to orthostatic hypotension or secondary to stroke or myocardial infarction, but there appears to be a clear relationship between orthostatic hypotension and death.[322,326,327]

Table 28-6 Approaches to Help Prevent Drug-Induced Hypotension[3,254,255,298]

- Avoid concurrent use of nitrates and phosphodiesterase type-5 inhibitors
- Elevate the head of the bed to a 5–20° angle
- Encourage mild-to-moderate exercise
- Initiate therapy with the lowest possible dose, administering the first dose at bedtime, and increasing the dose slowly
- Instruct the patient to arise slowly upon waking, allowing the feet to dangle over the side of the bed for a few seconds to minutes, before rising to a completely elevated stance
- Instruct the patient to avoid consuming large meals
- Instruct the patient to avoid situations that may potentially induce orthostatic hypotension (Table 28-5)
- Instruct the patient to consume 200–250 mg of caffeine (2 cups of coffee) with a meal
- Instruct the patient to eat low-carbohydrate foods
- Instruct the patient to eat sodium-containing foods and increase water intake
- Instruct the patient to minimize alcohol intake
- Obtain an extensive medical and medication history
- Use Jobst stockings, waist-high custom-fitted elastic stockings, and knee-length elastic stockings with an abdominal binder

PREVENTION

Strategies for prevention of drug-induced orthostatic hypotension are presented in **Table 28-6**.[3,254,255,298]

PHARMACOLOGIC STRATEGIES

In patients with one or more risk factors for drug-induced hypotension, there are certain measures that can minimize the risk. The drug with the lowest risk of orthostatic hypotension should be chosen and initiated at the lowest dose possible, with slow dose titration, and ideally administered at bedtime. Furthermore, for patients with multiple comorbidities, such as automonic dysfunction, heart failure, or diabetes, who are a fall risk or have multiple risk factors, then the first dose of the potentially causative drug should be administered in a controlled setting.

In patients receiving drugs that are associated with orthostatic hypotension, the risk can be reduced with drug-specific measures. If a diuretic is to be administered concomitantly with another antihypertensive agent, administration of the two drugs should be separated as much as possible.[328] In patients who experience histamine-related hypotension associated with vancomycin or the opioid derivatives, prophylactic administration of oral or intravenous histamine-1 receptor blockers may help prevent future episodes. Methylprednisolone may be administered 1 hour before the first and second doses of thymoglobulin to prevent cytokine-mediated hypotension.[272] Doses of atracurium and mivacurium should be divided or administered over 1–2 minutes, or both, to decrease the risk of histamine-related hypotension.[262] To reduce the risk of ACE inhibitor-induced hypotension, the initial dose of these drugs should be reduced by 50% if the pretreatment systolic blood pressure is ≤100 mm Hg; however, if the pretreatment systolic blood pressure is <90 mm Hg, therapy with an ACE inhibitor should be initiated only with caution and with careful monitoring.[307,308]

Within the inpatient setting, patients may experience acute hypotension associated with the use of intravenous vasodilatory inotropes such as milrinone, direct vasodilators such as hydralazine or nicardipine or mixed arterial/venous vasodilators such as nitroprusside or nesiritide. Kidney function should be taken into account when selecting initial doses of intravenous vasodilators that are eliminated renally, such as milrinone and nitroprusside. If symptomatic hypotension develops, doses of these intravenous agents should be titrated as low as possible to restore adequate hemodynamics, or therapy should be discontinued. Invasive blood pressure monitoring with an arterial catheter should be used to assess hemodynamic parameters and adjust doses of vasoactive agents if the patient develops cardiogenic shock.

NONPHARMACOLOGIC STRATEGIES

Other strategies to minimize the risk of drug-induced hypotension include elevating the head of the patient's bed to a 5–20° angle. This helps activate the renin-angiotensin-aldosterone system and reduces nocturnal diuresis while preserving interstitial fluid in the extremities.[42] Patients should arise slowly upon waking, allowing their feet to dangle over the side of the bed for a few seconds to minutes before rising to a completely elevated position. Situations that may potentially induce orthostatic hypotension should be avoided (Table 28-5).[255] If drug-induced hypotension is exacerbated by postprandial hypotension, symptoms can be minimized by reducing alcohol intake, eating low-carbohydrate foods, and avoiding large meals. By blocking adenosine receptors, consumption of two cups of coffee (200–250 mg of caffeine) with breakfast and lunch can increase systolic pressure by about 12 mm Hg and diastolic pressure by about 6 mm Hg.[329,330] Drinking caffeinated beverages around the clock increases the risk of tolerance to the caffeine; thus, consumption of caffeinated beverages are recommended in the morning and midday only. Exercise may be helpful in patients with poor orthostatic tolerance. Mild exercise may improve symptoms with minimal effects on resting blood pressure. Postural maneuvers may also be used to increase blood pressure. Leg crossing and squatting may allow patients to increase their blood pressure by as much as 13–44 mm Hg.[254,255,280,297,298]

Compression stockings, waist-high custom-fitted elastic stockings, and knee-length elastic stockings with an abdominal binder may help decrease venous pooling of blood. In patients with no contraindications, water and foods containing sodium can be consumed liberally.[254,255,298,331] As little as 240 mL of water may exert a pressor effect,resulting in seated blood pressure increasing within 5 minutes, peaking within 35 minutes, and persisting for 60 minutes or longer.[332-334]

MANAGEMENT

When possible, contributing factors should be eliminated, and the offending medication should be identified, discontinued, and replaced with another medication with a lower risk of hypotension. Because drug-induced hypotension may be directly related to a high therapeutic dose, overdose, or administration rate, management varies depending on the precipitant medication. **Table 28-7** provides specific recommendations for managing hypotension caused by specific drugs.[116,124,150-152,154-158,176,185,202,220,237,243,256,265,269,273,290,291,308,309,335-344]

Table 28-7 Medication-Specific Management for Drug-Induced Hypotension

Medication	Recommendation

ACE inhibitors[256]	Reduce or briefly discontinue diuretic and/or ACE inhibitor; restart at 50% of the dose
Amiodarone[116,335]	Reduce rate of IV infusion; may consider use of fluids or vasopressor or inotrope
Amifostine[202]	Place patient in the Trendelenburg position, discontinue amifostine, and initiate fluid infusion (saline); infusion duration >15 minutes is associated with a higher incidence of adverse effects
Antipsychotic agents[336-338]	Discontinue agent; restart at 25–50% of initial dose; in severe cases, begin fluid resuscitation or vasopressors (i.e., dopamine, epinephrine, norepinephrine)
Centrally acting α-adrenergic agonists[308,336]	Slowly decrease dose and discontinue agent; in severe cases, begin fluid resuscitation, vasopressors (i.e., epinephrine), or naloxone, or all of these
Direct-acting arterial vasodilators[309,336]	If severe, consider fluid resuscitation and/or vasopressors (i.e., dopamine)
Dopamine agonists[176,185]	Reduce dose
β-blockers[309,336]	Reduce dose of β-blocker, adjust dose of ACE inhibitor and diuretic, or both; if severe, consider fluid resuscitation and/or vasopressors (epinephrine or norepinephrine)
Epoprostenol[243,339]	Discontinue infusion and hypotension should resolve within 5 minutes; begin again at a slower rate
Etoposide[273]	If hypotension occurs, discontinue the infusion and, if necessary, administer fluids; infuse etoposide over at least 30–60 minutes
Fenoldopam[340]	Discontinue IV infusion and restart at slower rate and lower dose
Interleukin-2[273]	Use IV fluids judiciously; vasopressors such as dopamine or phenylephrine may be required
Levofloxacin[156]	Discontinue IV infusion and restart at slow rate (over 60 to 90 minutes)
Milrinone[237,341]	Consider fluid resuscitation, vasopressors (i.e., dopamine, norepinephrine, phenylephrine), or vasopressin (0.03–0.07 units/min)
Nesiritide[220]	Discontinue nesiritide and observe patient; once stabilized, restart therapy with no bolus at 30% of initial dose
Nitrates[309,336]	For IV, discontinue infusion and restart at a lower dose
Opiates[309,336]	Discontinue IV infusion and begin at a slower rate; pretreat with histamine antagonists; for severe hypotension, administer naloxone; avoid use of IV codeine
Pentamidine[154,155]	Patients should be supine and blood pressure monitored closely during and following administration until stable
Phenytoin[150-152,290,291] Fosphenytoin[150-152,290,291]	Reduce rate of IV infusion or discontinue the drug
Procainamide[124]	Reduce rate of IV infusion, lower the dose, or both
Tricyclic antidepressants[269,342]	Slowly decrease dose, then discontinue; consider alternative agent such as SSRI or nortriptyline; if severe, begin fluid resuscitation or vasopressors (i.e., dopamine, epinephrine)
Vancomycin[157,158,265,343,344]	Discontinue IV infusion and restart at slower rate; infuse over more than 1

	hour; fluids, antihistamines, or corticosteroids may also be considered

ACE = angiotensin-converting enzyme, IV = intravenous, SSRI = selective serotonin reuptake inhibitor.

If the initial management measures listed in Table 28-7 do not sufficiently correct hypotension, then drug treatment may be considered (**Table 28-8**).[340,345-382] With one exception noted below, drug treatment has not been studied in the setting of drug-induced hypotension.

Although fludrocortisone has not been directly evaluated for the treatment of drug-induced orthostatic hypotension, it is considered a treatment of choice for orthostatic hypotension.[383,384] Fludrocortisone is a potent mineralocorticoid with minimal glucocorticoid effects. Fludrocortisone may increase blood volume by stimulating renal sodium retention and vascular sensitivity to norepinephrine and by raising peripheral vascular resistance via enhancement of catecholamine release. The initial dose is 0.1 mg orally once daily, and the dose should be titrated upward based on efficacy every 1–2 weeks to a maximum dose of 1 mg/day; total daily doses exceeding 0.3 mg daily may not provide added benefit. The full therapeutic effect may require up to 1–2 weeks. Adverse effects include hypokalemia and hypomagnesemia, which may occur within the first 2 weeks of therapy. Headache, edema, weight gain, and supine hypertension may also occur. Despite the fact that fludrocortisone is used commonly for orthostatic hypotension, limited data exist regarding its efficacy, and some studies have questioned its value as compared with placebo.[362,363,385,386] If fludrocortisone is not tolerated or does not eliminate orthostatic symptoms, midodrine can be added in place of, or as adjunctive therapy to, fludrocortisone.[1,383]

Table 28-8 Drug Therapy Regimens Used to Treat Orthostatic Hypotension

Medication	Dose	Level of Evidence[a]
Atenolol[345,346]	50 mg PO daily	A
Atomoxetine[347]	18 mg PO daily	A
Clonidine[357,382,398,399]	0.4 mg PO twice daily	B
Desmopressin[348]	4 mcg IM at bedtime	B
Dihydroergotamine[349,350]	0.5–1 mg IM twice daily	A
Droxidopa[351-354]	100–600 mg PO 3 times daily	A
Ergotamine tartrate[355]	1–3 mg PO daily or twice daily	C
Ergotamine[356,357]	0.36–0.72 mg inhalation 2 or 3 times daily	A

Epoetin alpha[358-361]	25–75 units/kg sub-Q 3 times weekly	B
Fludrocortisone[362,363,b]	0.1–0.3 mg PO daily	A
Fluoxetine[364,365]	20 mg PO daily	B
Flurbiprofen[366,367]	50–200 mg PO 2–3 times daily	B
Indomethacin[368,369]	25–50 mg PO 3 times daily	B
Metoprolol[370]	50–100 mg PO twice daily	A
Midodrine[371,372,b]	2.5–10 mg PO 3 times daily	A
Paroxetine[375]	20 mg PO daily	A
Pindolol[376,377]	5 mg PO 3 times daily	B
Propranolol[340,378]	40–240 mg PO daily in 3–4 divided doses	C
Pyridostigmine[379]	60 mg PO daily	A
Yohimbine[380,381]	5 mg PO 2–3 times daily	B

IM = intramuscularly, PO = oral, sub-Q = subcutaneous.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Preferred therapy. Other drugs listed in this table reserved for hypotension refractory to fludrocortisone or midrodine.

Midodrine, a prodrug of desglymidorine, is a peripherally acting α-adrenergic agonist that constricts both the arterial and venous vasculature. This was the first U.S. Food and Drug Administration (FDA)-approved agent for the treatment of orthostatic hypotension and has demonstrated efficacy in small randomized, controlled trials.[371,372,387-391] However, in view of limited postmarketing effectiveness data, in 2012 the FDA requested the manufacturer of midodrine to conduct two trials, the results of which are pending.[392] The initial dose is typically 2.5 mg two to three times daily, which may be titrated upward by 2.5 mg three times daily at weekly intervals to a maximum total daily dose of 30 mg. The drug should be administered two or three times daily, with the last dose given 4 hours before bedtime to avoid supine hypertension. Other adverse effects include piloerection, pruritus, and tingling of the scalp.

Droxidopa, a synthetic norepinephrine precursor, is the second FDA-approved drug for the treatment of orthostatic hypotension, supported by evidence from several studies.[351-354] Most studies of droxidopa are in the setting of severe orthostatic hypotension often associated with autonomic disorders, such as Parkinson disease. The initial dose of droxidopa is 100 mg three times daily, titrated by 100 mg increments to achieve effect, or a maximum total daily dose of

1,800 mg. Adverse effects are mostly limited to supine hypertension; thus, the last dose should be administered 5 hours before bedtime.[393]

Pyridostigmine is a cholinesterase inhibitor that improves autonomic neurotransmission. The initial and maintenance dose of immediate-release pyridostigmine for orthostatic hypotension is 60 mg daily. Pyridostigmine has demonstrated efficacy as monotherapy or in combination with midodrine 2.5–5 mg once daily without increasing supine hypertension.[379] Pyridostigmine has also been studied in combination with yohimbine, but synergistic effects were not demonstrated.[394] Adverse effects associated with pyridostigmine include diaphoresis, hypersalivation, nausea, emesis, and diarrhea.

The ergot alkaloids ergotamine and dihydroergotamine administered parenterally, orally as a solid dosage form or via inhalation have shown some promise in improving blood pressure or venous pooling defects.[349,350,355,356,395] Dihydroergotamine has also demonstrated improvements specifically for drug-induced orthostatic hypotension resulting from antihypertensives and psychotropics.[396,397] In patients with refractory or severe orthostatic hypotension, therapy with the central α_2-adrenergic receptor agonist clonidine, the peripheral α_2-adrenergic receptor antagonist yohimbine, or the norepinephrine transporter blocker atomoxetine may be considered.[347,357,380-382,398-400] Although clonidine is generally thought to increase the risk of orthostatic hypotension, small studies suggest it may assist in raising blood pressure in patients with hypoadrenergic orthostatic hypotension by causing pronounced vasoconstriction.[382]

For patients with orthostatic hypotension and concurrent anemia, epoetin alpha may be a therapeutic option.[299,358-361] Epoetin alpha increases blood pressure, hematocrit, blood volume, and viscosity. Epoetin is especially helpful for patients with underlying anemia. Epoetin alpha is administered at a dose of 25–75 units per kilogram subcutaneously three times weekly with oral iron. Although there is no target hematocrit for the management of orthostatic hypotension, it is not recommended to exceed the normal ranges based on sex. It can be used as monotherapy or as an adjunct to other therapies. A risk and mitigation strategy (REMS) is no longer required for epoetin alpha, but possible adverse effects include edema, nausea, vomiting, and myalgia.[401]

Other adjunctive therapies include nonsteroidal anti-inflammatory drugs (NSAIDs). However, this approach is controversial. Although the true mechanism is unknown, NSAIDs are postulated to inhibit vasodilatory prostanoids and enhance vascular sensitivity to angiotensin II, thereby increasing peripheral vascular resistance. In addition, these agents cause sodium retention, thus increasing intravascular volume. Indomethacin 50 mg orally three times daily and flurbiprofen 50–200 mg orally two to three times daily, either alone or in combination with fludrocortisone, have each been shown to relieve symptoms of orthostatic hypotension and increase blood pressure.[366-369] However, indomethacin should be avoided, when possible, because of the increased risk of confusion. Further, chronic use of all NSAIDs should be used with caution in all patients because of the risk of cardiovascular, gastrointestinal, and renal adverse effects.

Oral propranolol or pindolol may reestablish sympathetic homeostasis in patients with low plasma catecholamine concentrations and impaired baroreceptor function.[340,376-378,402] Inhibiting α-adrenergic receptors allows plasma catecholamines to exhibit predominant effects on the vasoconstrictive β-adrenergic receptors. The efficacy of using β_1 selective β-blockers remains unclear.[345,346,370,403,404]

It has also been reported that 5-hydroxytripta-mine (serotonin) may play an important role in the modulation of central nervous system blood pressure and heart rate regulation; thus, fluctuations in central serotonin concentrations could play a role in the pathogenesis of neurocardiogenic vasovagal syncope. Robust data support the efficacy of paroxetine for improvement of symptoms in patients with vasovagal syncope who are unresponsive to or intolerant of traditional medications.[375] Fluoxetine has also demonstrated efficacy in treating refractory orthostatic hypotension.[364,365]

In summary, treatment of drug-induced orthostatic hypotension should begin with conservative, nonpharmacologic measures and resort to drug treatment only when necessary. With the exception of dihydroergotamine, drug treatments for drug-induced orthostatic hypotension have not been studied. However, extrapolating the body of evidence for treatment of orthostatic hypotension, fludrocortisone remains the initial choice for drug treatment for most patients with drug-induced orthostatic hypotension.

INFORMATION FOR PATIENTS

Patients susceptible to drug-induced hypotension and their care providers should be educated regarding the proper technique for measurement of blood pressure in both the supine and upright positions, acceptable blood pressure ranges, and medications that may cause hypotension.[3] Patients should be instructed that simply sitting or lying down quickly may alleviate symptoms of orthostatic hypotension. However, patients should be warned not to lie down for several hours after taking short-acting pressor agents. Patients taking antihypertensive medications should be instructed to always change their posture gradually, pausing for 10–30 seconds before arising from a seated position. If orthostatic hypotension develops in a seated position, patients should place their feet on a footrest. Several smaller meals rather than larger meals should be ingested to decrease the risk of postprandial hypotension. Patients should avoid excessive alcohol consumption, exposure to extended periods of heat, and remain well hydrated at all times. Because physical deconditioning may worsen orthostatic hypotension, healthcare providers may wish to encourage mild-to-moderate physical activity. Patient education handouts with patient-friendly information can also be useful.[405]

CHAPTER 29

Valvular and Pericardial Heart Disease

Sarah A. Spinler and Frank E. Silvestry

Although cardiovascular disease is the leading cause of death in the United States, valvular and pericardial disease remain relatively uncommon as compared with other cardiovascular diseases such as hypertension and ischemic heart disease. Valvular heart disease accounts for approximately 3.1% of all cardiovascular deaths in the United States.[1] Pericarditis is responsible for approximately 5% of emergency department visits for chest pain and results in 0.1% of hospital admissions.[2] Drug therapy may result in a wide variety of cardiovascular complications, including valvular heart disease and pericardial disease. Although more commonly a result of degenerative or rheumatic processes, valvular heart disease (which includes aortic, mitral, and tricuspid regurgitation) has been reported to occur in association with or as a result of drug therapy. Pericardial disease associated with drug therapy includes pericarditis due to drug-induced systemic lupus erythematosus (SLE)-like syndrome (with or without cardiac tamponade), acute pericarditis, constrictive pericarditis, and hemopericardium. This chapter will review the manifestations of drug-induced valvular and pericardial heart disease.

CAUSATIVE AGENTS

Drugs that have been reported to induce valvular or pericardial heart disease are listed in **Table 29-1**.[3-156] Three main drug classes that have been associated with the development of new valvular or pericardial heart disease are: ergot alkaloids (for migraine headache), ergot-derived dopamine agonists (for Parkinson disease), and 5-hydroxytryptamine (5-HT or serotonin) uptake regulators/inhibitors for weight loss. The earliest reports of drug-induced valvular heart disease appeared in the 1960s, in association with the ergot alkaloids ergotamine and methysergide.[16,17,23,62,63] The anorectic agents fenfluramine and its D-isomer dexfenfluramine, as well as fenfluramine in combination with phentermine, a combination commonly referred to as “fen-phen,” have been associated with left-sided regurgitant valvular lesions.[4-15,18-21] Both fenfluramine and dexfenfluramine were withdrawn from the U.S. market in 1997, after reports of valvular heart disease associated with these agents began to appear.[8,19] The ergot-derived dopamine agonists bromocriptine, cabergoline, and pergolide, used to treat Parkinson disease, have also been reported to result in both left- and right-sided valvular disease.[3,22,76-88,90-97,125-127] In 2006, the U.S. Food and Drug Administration (FDA) ordered the inclusion of a black box warning in pergolide’s labeling regarding the potential for valvular heart disease. The drug was voluntarily withdrawn from the U.S. market in 2007 amid continuing reports of this drug-induced disease. Cabergoline, when used at lower doses for the treatment of prolactinoma and acromegaly, has not been associated with valvulopathy.[157-165] A multicountry nested case-control study found that pergolide and cabergoline were both associated with significant valvulopathy in patients with Parkinson disease but not when used for treatment of hyperprolactinemia.[163] This may be due to lower weekly and cumulative doses used in the treatment of hyperprolactinomas.[161] In 2007, the European Medicines Agency added a warning about valvulopathy to the labeling of all ergot alkaloids and restricted the maximum dose of cabergoline and bromocriptine to 3 mg/day and 30 mg/day, respectively.[166-168] In August 2011, the FDA added a cardiac valvulopathy warning to the product labeling of cabergoline.[169,170] The product label recommends a maximum dose of 1 mg twice weekly for treatment of prolactinomas and baseline echocardiography to exclude significant valvular disease (a contraindication to use) as well as echocardiograms every 6–12 months and diagnostic monitoring using chest x-ray and computed tomography (CT) scan if clinical signs and symptoms such as edema, new cardiac murmur, dyspnea, or heart failure appear.

Table 29-1 Agents Implicated in Drug-Induced Valvular and Pericardial Heart Disease

Drug	Incidence	Level of Evidence[a]
AORTIC REGURGITATION		
Bromocriptine[3,97,125]	NK	B
Cabergoline[77,79,80,86-91,97,126,127]	16.7–68.8%	B
Dexfenfluramine[4-15]	6.6–38%	B
Dexfenfluramine in combination with phentermine[4-15]	6.6–38%	B
Ergotamine[16,17]	NK	C
Fenfluramine[4-15,18-21]	6.6–38%	B
Fenfluramine in combination with phentermine[5-15,18-21]	6.6–38%	B
MDMA[98]	14%	B
Methysergide[59,62,63]	0.02%	B
Pergolide[22,76-78,80,81,82-88,90-97,127]	0.005–67%	B
MITRAL REGURGITATION		
Bromocriptine[3,97,125]	NK	C
Cabergoline[77,80,86-91,97,126,127]	28.6–68.8%	B
Dexfenfluramine[4-15]	1.3–3.5%	B
Dexfenfluramine in combination with phentermine[4-15]	1.3–3.5%	B
Ergotamine[16,17,23]	NK	C
Fenfluramine[4-15,18-21]	1.3–3.5%	B
Fenfluramine in combination with phentermine[4-15,18-21]	1.3–3.5%	B
MDMA[98]	14%	B
Methysergide[59,62,63]	0.02%	B
Pergolide[22,76-78,80-88,90-97,127]	0.005–75%	B
TRICUSPID REGURGITATION		
Bromocriptine[3,97,125]	NK	C
Cabergoline[80,88,126,127]	NK	B
Ergotamine[16,23]	NK	C
MDMA[98]	NK	C
Methysergide[59,62,63]	0.02%	B

Pergolide[22,76-78,80-88,90-97,127]	0.005–78%	B
MITRAL STENOSIS		
Ergotamine[16,17,23]	NK	C
Methysergide[59,62,63]	NK	B
ACUTE EFFUSIVE PERICARDITIS		
Adalimumab[155,156]	NK	C
Azactidine[124]	NK	C
Balsalazide[137,138]	NK	C
Busulfan[24,25]	NK	C
Clozapine[99-109,156-159]	NK	B
Cromolyn sodium[26]	NK	C
Cyclophosphamide[24,27,28,141]	NK	C
Cytarabine[24,29-31]	NK	C
Dantrolene sodium[32,33]	NK	C
Daunorubicin[24,34]	NK	C
Doxorubicin[24,34]	NK	C
5-flurouracil[144,145]	NK	C
Hydralazine (secondary to SLE-like syndrome)[35-37]	2%	C
Isoniazid (secondary to SLE-like syndrome)[38,39,128]	30%	C
Methyldopa (secondary to SLE-like syndrome)[40]	NK	C
Mesalazine (mesalamine)[75,112-122,134-136]	NK	C
Methotrexate[110,111,130,131]	NK	C
Minoxidil[41-44]	3.8–20%	C
Phenylbutazone[45]	NK	C
Phenytoin (secondary to SLE-like syndrome)[35]	NK	C
Procainamide (secondary to SLE-like syndrome)[48-53]	18–57%	C
Sulfasalazine[112,123]	NK	C
Tretinoin[24,54]	NK	C
CONSTRICTIVE PERICARDITIS		
Cyclophosphamide[55]	NK	C
	NK	C

Cytarabine[56]		
Ergotamine[57]	NK	C
Methysergide[58-63]	0.02%	C
Procainamide (secondary to SLE-like syndrome)[48]	NK	C
HEMOPERICARDIUM		
Apixaban[148]	NK	C
Busulfan[64]	NK	C
Dabigatran[149-152]	NK	C
Fibrinolytics[65-71]	8.75–42%	C
Rivaroxaban[153-154]	NK	C
Vitamin K antagonists (oral)[72-74]	NK	C

MDMA = methylenedioxymethamphetamine, NK = not known, SLE = systemic lupus erythematosus.

[a]Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

Acute pericarditis has been associated with a wide variety of drugs (Table 29-1), including those that may induce the syndrome resembling SLE (hydralazine, isoniazid, methyldopa, phenytoin, procainamide), cancer chemotherapy drugs (busulfan cyclophosphamide, cytarabine, methotrexate, doxorubicin, daunorubicin, tretinoin, 5-flurouracil, azacitidine), and other drugs including mesalazine (mesalamine), sulfasalazine, balsalazide, infliximab, adalimumab, minoxidil, dantrolene sodium, phenylbutazone, cromolyn sodium, and interferon alpha.[4,24-54,75,109-122,124,128-143,155,156] Clozapine has been associated with pericarditis, often in conjunction with myocarditis.[99-109,144-147] Constrictive pericarditis has been reported in association with ergotamine, methysergide, cyclophosphamide, cytarabine, and procainamide.[48,55-63] Finally, hemopericardium, with or without pericarditis, has been described after fibrinolytic therapy for acute myocardial infarction or stroke, during busulfan therapy (in conjunction with severe thrombocytopenia), during therapy with vitamin K antagonist anticoagulants such as warfarin, and more recently with the direct-acting oral anticoagulants apixaban, dabigatran, and rivaroxaban.[64-74,148-154]

EPIDEMIOLOGY

There are no available estimates of the overall incidence or frequency of drug-induced valvular or pericardial diseases. However, incidences of pericardial effusion due to minoxidil, pericarditis in patients with drug-induced SLE, valvular disease with long-term ergot alkaloid therapy, hemopericardium after fibrinolysis for myocardial infarction, and regurgitant valvular disease induced by anorectic agents have all been described relatively well.

The incidence of pericardial effusion occurring during minoxidil therapy ranges from 3.8% (73 of 1,919 patients) to 20% (1 of 5) depending on the population studied, with a higher frequency in patients with kidney disease.[41,43] The prevalence of acute pericarditis in those with idiopathic SLE ranges from 30% to 45%.[48] Reported rates of acute pericarditis complicating drug-induced SLE are similar to those associated with idiopathic SLE; the incidences of acute pericarditis associated with isoniazid and procainamide are approximately 30% and 18–57%, respectively.[48] Pericarditis in patients with SLE-like syndrome secondary to hydralazine and methyldopa is relatively uncommon.[37,40] Cardiac tamponade occurring in patients with idiopathic or drug-induced SLE is rare.[36,37]

Although the vascular complications associated with ergot alkaloid treatment have been known for well over a century, the frequency of valvular disease is less well characterized. Early reports relied on auscultatory findings, which are less sensitive than echocardiography in the detection of valvular disease. Graham and colleagues[62,63] estimated that the incidence of methysergide-associated valvular disease is 1 in 5,000 patients treated.

The incidence of echocardiographically detected pericardial effusion and hemopericardium after fibrinolysis is highly variable, ranging from 8.75% in 80 consecutive patients treated with streptokinase to 24% in 112 patients treated with alteplase.[69,71] In a study of 192 patients who underwent serial echocardiography on days 1, 5, 10, and 21 and then annually for 3 years, pericardial effusion was detected at least once in 43% of patients, and the incidence was similar in those who received fibrinolytics (42%) and those who did not (50%).[70] The frequency of pericardial effusion varies depending on the duration of echocardiographic follow-up, with an increasing frequency occurring during the first 5 days after myocardial infarction, regardless of whether fibrinolytic drugs were administered.[70]

The best-studied example of drug-induced valvular heart disease is that of mitral and aortic regurgitation caused by the anorexiant agents fenfluramine and dexfenfluramine. In 1997, the FDA defined anorexiant drug–related cardiac valvulopathy as moderate or greater mitral regurgitation, mild or greater aortic regurgitation, or both detected on a standard echocardiogram, in the absence of other known causes of valvular disease. Patients with these drug-related findings are defined as FDA-positive.[8] Using that definition, the reported prevalence of fenfluramine-associated and dexfenfluramine-associated valvular disease ranged from <0.1% to 38%, depending on the population studied and method used.[8,9] Assessing data only from controlled studies, the incidence of FDA-positive valvular heart disease associated with anorexiant drugs varies from 1% to 15%, which is still significantly higher than that reported in controls (3–6%).[5,6,171,172] Aortic regurgitation occurs more frequently than mitral regurgitation.[6,77,78] A prospective study did not find an association between phentermine (when taken without fenfluramine or dexfenfluramine) and valvulopathy, and as a result, phentermine remains currently used as monotherapy.[5,10] Moderate-to-severe cardiac valvular regurgitation associated with ergot alkaloids in patients with Parkinson disease has also been well studied. Case-control studies comparing the frequency of cardiac valvular disease with ergot drugs (pergolide, cabergoline) to either nonergot drugs (such as ropinirole or pramipexole) or controls report a frequency of 18–37% in ergot-treated patients, 0–25% in non-ergot-treated patients and 4–18% in controls, with ergot-treated patients at increased risk of valvular heart disease.[79-81,83,84,87,93,94,126,127]

MECHANISMS

There are a number of proposed mechanisms for drug-induced valvular and pericardial heart disease (**Table 29-2**). A common link between valvular regurgitation after ergotamine, methysergide, fenfluramine, and dexfenfluramine is that these agents (and their metabolites) are similar structurally to serotonin and are potent agonists of the 5-hydroxytryptamine $(HT)_{2B}$ subtype of serotonin receptor, which promotes serotonin release.[5,7,173-175] 5-HT exerts a direct mitogenic transcriptionally controlled proliferative effect on cardiac valve vascular interstitial cells.[176,177] Excessive cell division and proliferation leads to cell overgrowth resulting in valve dysfunction.

Table 29-2 Mechanisms of Drug-Induced Valvular and Pericardial Heart Disease

Drug	Mechanism
Alteplase, reteplase, streptokinase, tenecteplase (hemopericardium)	Fibrinolytic effect coupled with pericarditis caused by myocardial infarction
Fenfluramine, dexfenfluramine (valvulopathy) Ergotamine (valvulopathy) Pergolide (valvulopathy) Cabergoline (valvulopathy) MDMA (valvulopathy)	Activation of the 5-HT_{2B} subtype of serotonin receptor, which promotes serotonin release

HT = hydroxytryptamine, MDMA = methylenedioxymethamphetamine.

The type of valvular lesions observed in association with these agents is similar to that observed in patients with carcinoid heart syndrome, which is also associated with high concentrations of circulating serotonin.[5] Human cardiac valves express large numbers of 5-HT$_{2B}$ receptors and no appreciable 5-HT$_{2C}$ receptors.[80] Examination of affected native valves excised after valve-replacement surgery reveals glistening white leaflets and chordae covered with a thick coating; however, underlying structures in the valves are preserved. On histologic examination, there is a proliferation of myofibroblasts with deposition of abundant extracellular matrix. Echocardiography has defined diastolic doming and anterior leaflet thickening with affected mitral valves. Leaflet mobility is preserved in the anterior leaflets but is impaired in the posterior leaflets.[6,16] Animal models suggest that activation of the 5-HT$_{2B}$ receptor and decreased 5-HT transporter gene activity (resulting in reduced 5-HT clearance and processing at the receptor) are associated with valvulopathy. Pergolide, cabergoline, and bromocriptine are derivatives of ergotamine and are also 5-HT$_{2B}$ receptor agonists.[178-180] Bromocriptine has a lower receptor-binding affinity and is a partial agonist of the 5-HT$_{2B}$ receptor, which may be the reason that there are fewer and only inconsistent reports of valvulopathy associated with this drug.[77,79,97,180] Lorcaserin, a weight-loss medication that is a specific agonist of 5-HT$_{2C}$, has not been associated with valvulopathy.[176,181] For unknown reasons, the valvulopathy observed with methysergide, ergotamines, fenfluramine, and dexfenfluramine is more often left-sided, while that associated with pergolide and cabergoline is right-sided.[178] Drugs with serotonergic activity but lacking activation of the 5-HT$_{2B}$ receptor, such as selective serotonin-reuptake inhibitors, triptans (5-HT$_{1B}$ and 5-HT$_{1D}$ receptor antagonist), or ondansetron (5-HT$_3$ antagonist), have not been associated with cardiac valvulopathy.[178]

Interestingly, 3,4-methylenedioxymethamphet-amine (MDMA, or “ecstasy”) also binds to and stimulates serotonin 5-HT$_{2B}$ receptors, producing an in vitro mitogenic response in cardiac valvular interstitial cells that is identical to that induced by fenfluramine.[175] One case-control echocardiographic study comparing the frequency of valvular heart disease using the FDA criteria for appetite-suppressant-induced valvular heart disease in users of MDMA (mean duration of use, 6.1 years) found an alarming incidence of 28% (8 of 29) in these young adults, as compared with 0% (0 of 28) among nonuser controls.[98] There has been a single published case report of pulmonary hypertension and severe mitral stenosis and regurgitation requiring valve replacement in a patient reporting chronic ecstasy use.[182]

Acute pericarditis and pericardial effusion occurring in patients with drug-induced SLE-like syndrome are pathologically indistinguishable from those occurring in association with idiopathic SLE. A more detailed discussion of the proposed mechanisms of drug-induced SLE-like syndrome may be found in Chapter

7. Pericarditis associated with mesalamine therapy has been postulated to be a type IV hypersensitivity reaction; there is an anamnestic response to re-exposure with recurrence on subsequent exposure to sulfasalazine.[75] The association of dantrolene with development of concomitant pleural and pericardial effusions and eosinophilia also suggests an allergic-type reaction.[32] Pericarditis and pericardial effusion associated with cancer chemotherapy in the absence of pericardial metastases are believed to be caused by an inflammatory reaction secondary to direct cytotoxicity, an immune-mediated hypersensitivity process, or both.[24,29,34]

Hemopericardium in patients with acute myocardial infarction who are treated with fibrinolytics is believed to be due to the antithrombotic effect of the fibrinolytic agent coupled with pericarditis caused by the myocardial infarction. However, at least one case of fibrinolytic-associated hemopericardium with cardiac tamponade has been reported after treatment of acute ischemic stroke with alteplase in the absence of myocardial infarction.[68] Hemopericardium associated with administration of the oral vitamin K antagonist warfarin occurs most often, but not exclusively, in the setting of underlying pericarditis or after cardiac surgery and is believed to be due to the drug's anticoagulant effect.[72,74]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Symptoms associated with drug-induced valvular and pericardial heart disease are similar to those of nondrug-induced disease and may occur at any time after initiation of therapy (**Table 29-3**). Patients with drug-induced valvular disease may present with a murmur on auscultation, signs of atrial or ventricular enlargement or dysfunction, fatigue, exercise intolerance, dyspnea on exertion, peripheral or pulmonary edema, as well as other signs of acute or chronic heart failure.[178,183,184] Many patients have no symptoms or obvious physical findings. Those with tricuspid regurgitation present with right-sided heart failure, symptoms of peripheral edema, ascites, hepatomegaly, jugular venous distention, or any combination of these.[184] Patients with drug-induced valvular disease may also present with endocarditis.[183,184] Individuals with drug-induced pericarditis may present with an enlarged cardiac silhouette, suggesting pericardial effusion on chest radiography, a characteristic pericardial friction rub on auscultation, dyspnea, pulsus paradoxus, cough, abdominal distention secondary to hepatic congestion, and a characteristic pleuritic chest pain that radiates to the scapula or jaw, worsens on inspiration or when laying supine and improves when leaning forward.[2] A 12-lead electrocardiogram (ECG) may reveal PR segment depression (except in lead aVR, where the PR segment may be elevated) and diffuse concave upward ST-segment elevation, as is observed in patients with other causes of acute pericarditis. Pleural effusion may also accompany pericardial effusion. Markers of inflammation such as C-reactive protein, erythrocyte sedimentation rate, and white blood cell count may also be elevated. If concomitant myocarditis is present, serum troponin concentrations may also be increased.[2] Cardiac magnetic resonance imaging (MRI) should be performed in patients with suspected concomitant myocarditis.[2] Other causes of pericarditis, such as infection, autoimmune disorders (e.g., SLE, sarcoidosis or amyloidosis) or malignancy, may be excluded using cardiac MRI, pericardiocentesis, and cell cytology. Percutaneous pericardial biopsy is often performed in conjunction with pericardiocentesis and reveals fibrosis and nonspecific inflammation. Patients with pericarditis and pericardial effusion secondary to SLE-like syndrome may also present with signs and symptoms of SLE, which are described in more detail in Chapter 7. Those with ergot-induced valvular or pericardial heart disease may also present with concomitant retroperitoneal fibrosis.[58,89,185] Patients with cardiac tamponade typically present with tachycardia, tachypnea, pericardial effusion, pulsus paradoxus, diffuse low voltage on 12-lead ECG, and clinical signs of hemodynamic compromise, such as hypotension. In addition, they may present with cardiogenic shock or cardiac arrest with pulseless electrical activity.[2]

Table 29-3 Signs and Symptoms Associated with Valvular and Pericardial Heart Disease

Valvular heart disease

- Atrial and ventricular enlargement on physical examination, echocardiogram, or both
- Dyspnea at rest or on exertion
- Murmur characteristic of the involved valve(s) detected on auscultation
- Signs and symptoms of endocarditis
- Signs and symptoms of heart failure, including peripheral edema, ascites, hepatomegaly, venous distention, rales

Acute and constrictive pericarditis

- Abdominal distention
- Chest pain
- Concomitant pleural effusion
- Cough
- Dyspnea
- Pericardial friction rub on auscultation
- PR segment depression (except in lead aVR, where PR segment may be elevated) and diffuse ST segment elevation on 12-lead electrocardiogram
- Pulsus paradoxus
- Retroperitoneal fibrosis (ergotamine, methysergide, pergolide, cabergoline)
- Signs and symptoms of systemic lupus erythematosus-like syndrome

Pericardial tamponade

- Cardiac arrest with pulseless electrical activity

- Diffuse low voltage on 12-lead electrocardiogram
- Feeling of apprehension
- Pericardial effusion
- Pulsus paradoxus
- Signs of hemodynamic compromise such as hypotension or cardiogenic shock
- Tachycardia

All patients with suspected drug-induced valvular or pericardial disease should undergo full transthoracic echocardiography with Doppler interrogation of the valves. Transesophageal echocardiography may be used if the transthoracic study is nondiagnostic because of technical limitations. Calcification, stenosis, and rheumatic thickening of the valves are generally absent. Examples of echocardiographic findings in patients with anorexiant-associated valvulopathy are shown in **Figure 29-1**, **Figure 29-2**, and **Figure 29-3**, and cardiac tamponade associated with drug-induced SLE-like syndrome is shown in **Figure 29-4** and **Figure 29-5**.

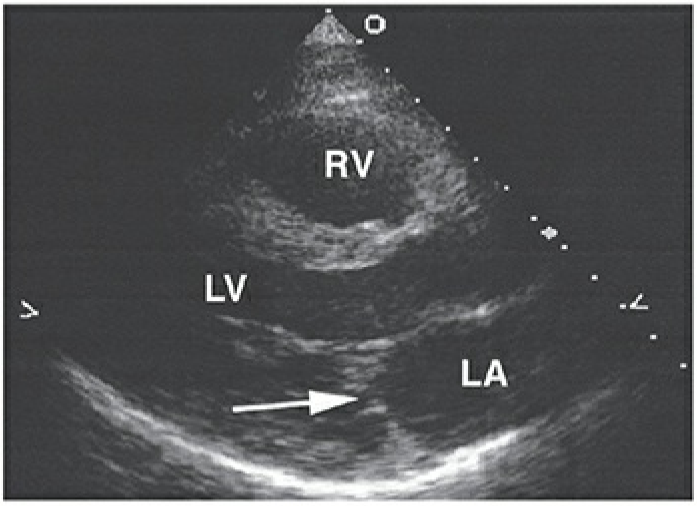

FIGURE 29-1 Transthoracic Echocardiogram from the Parasternal Window in the Long Axis

Demonstrating a normal left atrium (LA), left ventricle (LV), and right ventricle (RV) with mild thickening and restriction of the posterior mitral-valve leaflet (arrow). A finding that is typical of anorexiant-induced valvulopathy.

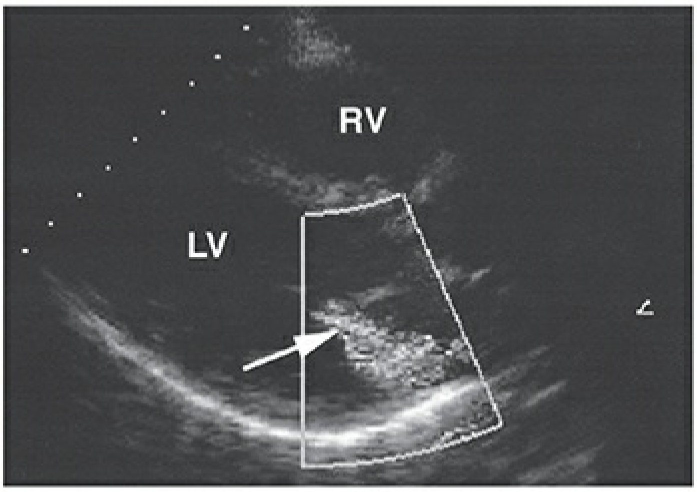

FIGURE 29-2 Transthoracic Echocardiogram with Doppler Map from the Parasternal Window in the Long Axis of the Same Patient as in Figure 29-1

Demonstrating a jet of moderate mitral regurgitation (arrow) directed slightly posteriorly, due to mild restriction of the posterior leaflet, as is characteristic of anorexiant-induced valvulopathy. LV = left ventricle, RV = right ventricle. (See color section.)

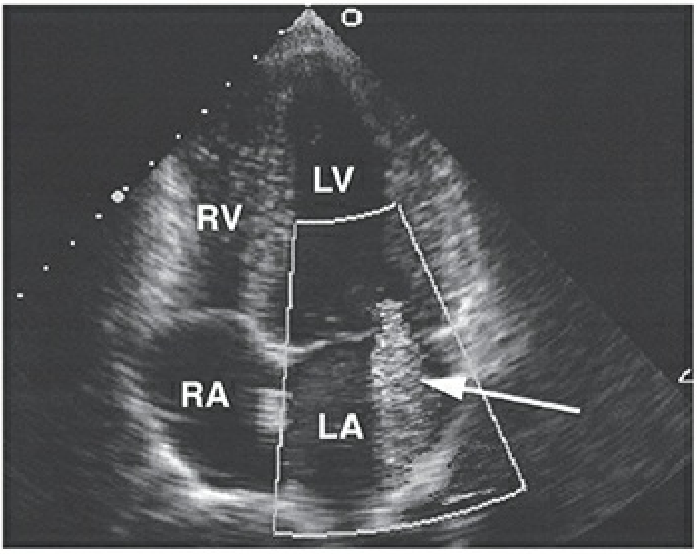

FIGURE 29-3 Apical 4-Chamber View from a Transthoracic Echocardiogram from the Same Patient as in Figures 29-1 and 29-2

Demonstrating a jet of moderate mitral regurgitation (arrow) directed slightly posteriorly and laterally, due to mild restriction of the posterior leaflet, characteristic of anorexiant-induced valvulopathy. LA = left atrium, LV = left ventricle, RA = right atrium, RV = right ventricle. (See color section.)

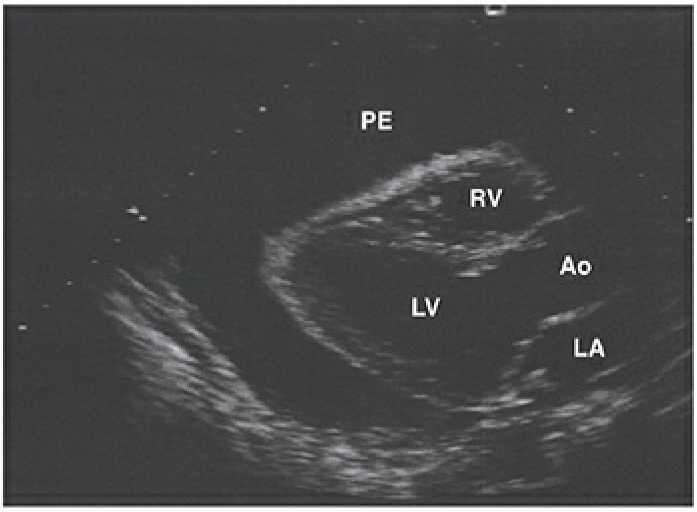

FIGURE 29-4 Transthoracic Echocardiogram from the Parasternal Window Demonstrating a Large Circumferential Pericardial Effusion (PE) Surrounding the Heart

In a patient with a drug-induced syndrome resembling systemic lupus erythematosus and who subsequently progressed to massive pericardial effusion with tamponade. Note the small and underfilled left atrium (LA), left ventricle (LV), and right ventricle (RV). Ao = aorta.

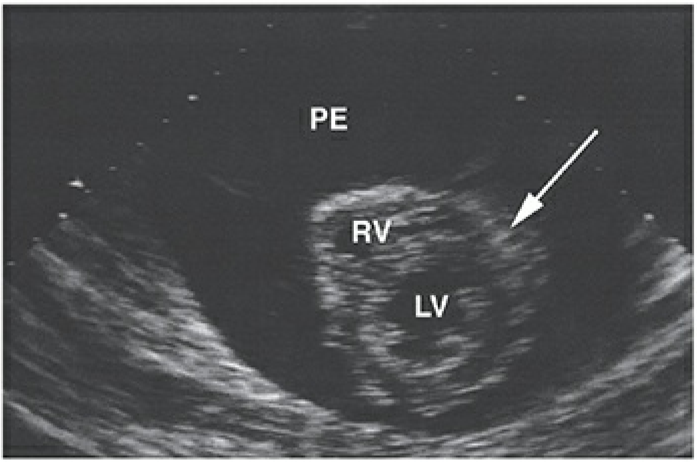

FIGURE 29-5 Transthoracic Echocardiogram from the Parasternal Window of the Heart in Short Axis

Demonstrating a Large Circumferential Pericardial Effusion (PE) Surrounding the Right Ventricle (RV) and Left Ventricle (LV). In a patient with a drug-induced syndrome resembling systemic lupus erythematosus and who subsequently progressed to massive pericardial effusion with tamponade. Note the thickened visceral pericardium (arrow), which is typical of patients with inflammatory PE.

Conditions to consider in the differential diagnosis of drug-induced valvular or pericardial disease are presented in Table 29-4. All patients presenting with suspected drug-induced valvular disease should undergo evaluation to exclude the diagnosis of carcinoid tumor using a 24-hour urine collection for determination of 5-hydroxy-indolacetic acid excretion, serum analysis of chromogranin A, as well as radiologic imaging to exclude the presence of a primary tumor or liver metastases.[3,186] Alternative causes of mitral regurgitation should be excluded, including myxomatous degeneration of the mitral valve, infective endocarditis, rheumatic heart disease, idiopathic SLE, amyloidosis, congenital heart disease, papillary muscle rupture, Marfan syndrome, and hypertrophic cardiomyopathy.[183-185,187] Other causes of aortic regurgitation should be excluded, including congenital abnormality of the aortic valve, calcific degeneration, rheumatic disease, myxomatous proliferation, infective endocarditis, aortic dissection, Marfan syndrome, and traumatic injury.[183-185,187]

Table 29-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Valvular and Pericardial Heart Disease

All valvular heart disease

- Carcinoid syndrome

Mitral regurgitation

- Amyloidosis
- Congenital heart disease
- Hypertrophic cardiomyopathy
- Infective endocarditis
- Marfan syndrome
- Myxomatous degeneration
- Papillary muscle rupture
- Rheumatic heart disease
- Systemic lupus erythematosus

Aortic regurgitation

- Aortic dissection
- Calcific degeneration
- Congenital heart disease
- Infective endocarditis
- Marfan syndrome
- Myxomatous proliferation
- Rheumatic heart disease
- Traumatic injury

Tricuspid regurgitation

- Cardiac tumor
- Collagen vascular disease
- Congenital heart disease
- Fabry disease
- Gout
- Heart failure with preserved ejection fraction
- Heart failure with reduced ejection fraction
- Intrinsic pulmonary disease
- Left ventricular dysfunction

- Mitral stenosis
- Mucopolysaccharidosis
- Pulmonary hypertension
- Rheumatic heart disease
- Rheumatoid arthritis
- Whipple disease

Pericardial tamponade

- Acute or constrictive pericarditis
- Bacterial infection
- Fungal infection
- Malignancy
- Myocardial infarction
- Neoplasm
- Trauma
- Tuberculosis
- Uremia
- Viral infection
- Collagen vascular disease

Other diseases causing tricuspid regurgitation that should be considered include left ventricular dysfunction, heart failure (either with reduced ejection fraction or with preserved ejection fraction), cardiac tumors, pulmonary hypertension, mitral stenosis, congenital heart diseases such as Ebstein's anomaly, rheumatic heart disease, collagen vascular diseases, and pulmonary diseases such as chronic obstructive pulmonary disease.[183-185,187] Patients with mitral stenosis should be evaluated for rheumatic heart disease and other degenerative valvular diseases in addition to carcinoid syndrome, including Fabry disease, mucopolysaccharidosis, Whipple disease, gout, and rheumatoid arthritis.[183,187] The diagnoses of malignancy, trauma, and uremia should be considered in patients presenting with cardiac tamponade.[183,187,188] Viral, bacterial, and fungal infections, as well as tuberculosis, uremia, myocardial infarction, neoplasm, trauma, and collagen vascular disease should be considered in patients presenting with acute or constrictive pericarditis.[183,187]

RISK FACTORS

Risk factors for certain types of drug-induced valvular and pericardial heart disease have been identified (**Table 29-5**). Risk factors for the development of mitral or aortic regurgitation associated with fenfluramine and dexfenfluramine include duration of therapy, dose, older age, and female sex.[6,189] Exposure to fenfluramine or dexfenfluramine for <3 months is associated with a lower incidence of valvulopathy than that associated with treatment durations >6 months.[13,21,171,190] Doses of either fenfluramine or dexfenfluramine >60 mg/day have also been associated with the development of valvular regurgitation.[21] Continuous use of methysergide or ergotamine for >9 months, rather than episodic use, has been associated with the development of valvulopathy.[23,58] Larger doses of ergotamine (>6 mg/day) and methysergide (>8 mg/day) have been associated with the development of valvular heart disease.[23,57,58] In a transthoracic echocardiographic study of 78 patients with Parkinson disease, the incidence of valvulopathy was higher in those who received cumulative doses of pergolide of 4,400 g compared with patients who received cumulative doses of 2,200 g.[76] Another case-control analysis suggested that even lower cumulative doses of either pergolide or cabergoline were associated with left-sided valvulopathy.[77] In that study, age, male sex, history of hypertension, and duration of use of either pergolide or cabergoline were risk factors.[77] Several other case-control studies[79,80,84,87,91-93] have found a positive relationship between either cumulative dose or duration of therapy with pergolide or cabergoline and risk of valvulopathy, although conflicting data exist.[85,90,94] When cabergoline is used for treating prolactinomas, doses are approximately one-tenth those used to treat Parkinson disease, and valvulopathy has not been observed.[157-165] Male sex, older age, and hypertension were found to be risk factors for the development of drug-induced valvulopathy in patients with Parkinson disease.[191]

Table 29-5 Risk Factors for Drug-Induced Valvular and Pericardial Heart Disease

Valvular heart disease associated with fenfluramine and dexfenfluramine

- Doses >60 mg
- Duration of use >3 months
- Female sex
- Older age

Valvular heart disease associated with ergotamine and methysergide

- Continuous use rather than episodic use
- Ergotamine dose >6 mg/day
- Methysergide dose >8 mg/day
- Duration of use >9 months

Valvular heart disease associated with pergolide and cabergoline

- Cabergoline dose >2 mg/day
- Cumulative dose >1,000 mg (applies to both pergolide and cabergoline)
- Hypertension
- Longer duration of use
- Male sex

Pericarditis associated with chemotherapy

- High doses
    - Cyclophosphamide cumulative dose ≥174 mg/kg
    - Cytarabine dose ≥3 g/m^2

Pericardial effusion associated with minoxidil

- Chronic kidney disease

Hemopericardium associated with fibrinolytic therapy and vitamin k antagonists

- Excessive anticoagulation (dose)
- Presence of pericarditis or pericardial effusion
- Recent cardiothoracic surgery

Single doses or initial courses of cancer chemotherapy with any of the agents listed in Table 29-1 may cause pericarditis occurring early (within hours to 1 month) after initial treatment. Higher doses of cancer chemotherapy agents are associated with a greater risk of cardiotoxicity.[11,24,25,28,31,55] Mean total cyclophosphamide doses of 174 mg/kg were associated with a higher rate of pericarditis compared with that associated with a cumulative dose of 87 mg/kg.[28] High doses of cytarabine (≥3 g/m^2) have been associated with pericarditis and heart failure symptoms occurring as early as after the first dose.[24] Minoxidil-associated pericardial effusion has been reported more frequently in patients with chronic kidney disease than in those with normal kidney function.[41]

Risk factors for the development of hemopericardium after fibrinolytic therapy include concomitant underlying pericarditis and pericardial effusion.[65] Pericarditis, excessive anticoagulation, and recent cardiac surgery are risk factors for the development of hemopericardium associated with oral vitamin K antagonist therapy.[72,74]

MORBIDITY AND MORTALITY

After cessation of therapy with fenfluramine and dexfenfluramine, approximately 50% of valve lesions stabilize, approximately 30% improve, and <10% worsen over a subsequent 6-month to 1-year period.[4-6,14,18,107,192] In the largest reported case series to date, Dahl et al. reported the outcomes of 5,743 previous fenfluramine users. In their single-center study, aortic regurgitation stabilized in 63%, worsened in 15%, and improved in 22% while mitral regurgitation stabilized in 47%, worsened in 25%, and improved in 28% of patients monitored during a mean follow-up of 30 months.[190] Outcomes after discontinuation of therapy with ergot derivatives in patients with Parkinson disease are not well studied, and no conclusions can be made.[76,192]

Most cases of drug-induced pericarditis are self-limited and resolve within 2–4 weeks after discontinuation of therapy with the offending agent. Although extremely rare, death may occur secondary to cardiogenic shock in patients with drug-induced cardiac tamponade as well as after valve-replacement surgery in patients with drug-induced valvular disease.[8,24,43]

PREVENTION

There are no specific recommendations to prevent drug-induced valvular or pericardial heart disease. Some general suggestions for the prevention of valvular or pericardial heart disease are listed in **Table 29-6**. Fenfluramine and dexfenfluramine have been removed from the U.S. and European markets, and ergot therapy for migraine has been supplanted by selective 5-HT$_1$ receptor agonist therapy. When possible, selective 5-HT$_1$ receptor agonists should be selected for treatment. Pergolide has been removed from the U.S. market. Nonergot dopamine agonists, either ropinirole or pramipexole, should be selected to treat Parkinson disease, as those agents do not bind substantially to the 5-HT$_{2B}$ receptor.[180] Patients receiving cabergoline for prolactinoma should undergo a baseline echocardiogram, with repeat echocardiograms every 6–12 months or when symptoms occur.[170] Patients with kidney disease taking minoxidil should be monitored more closely for clinical signs of pericarditis. The diagnosis of pericarditis should be excluded clinically before the administration of fibrinolytic agents, and anticoagulant doses should be monitored carefully, especially in patients undergoing cardiothoracic surgery, to prevent hemopericardium.

Table 29-6 Approaches to Help Prevent Drug-Induced Valvular and Pericardial Heart Disease

- Cabergoline (valvulopathy)—limit dose to <2 mg/day (maximum 1 mg twice weekly recommended for treatment of prolactinoma)
- Ergotamine (valvulopathy)—administer episodically and limit treatment duration to <9 months
- Fibrinolytic therapy (hemopericardium)—exclude the diagnosis of pericarditis before administering to patients with acute myocardial infarction
- Minoxidil (pericarditis/pericardial effusion)—monitor closely for signs and symptoms of pericarditis in patients with kidney disease

MANAGEMENT

Management of drug-induced valvular or pericardial heart diseases should be individualized based on the specific type and severity of cardiac disease. Treatment options for the management of drug-induced valvular and pericardial diseases are presented in **Table 29-7**.

Whether all patients who are exposed to a drug with the potential to induce valvular heart disease require an initial screening echocardiogram is not known. It is prudent for clinicians to maintain a high index of suspicion and to screen patients carefully for potential cardiac symptoms, cardiac murmurs on auscultation, or ECG abnormalities. If drug-associated valvulopathy is suspected, therapy with the suspected culprit agent should be discontinued. Serial echocardiography should be performed every 6–12 months to monitor for progression of valvular disease if significant disease is identified at the time of the baseline exam.[9] The most recent valvular heart disease guidelines from the American College of Cardiology/American Heart Association are not specific regarding diagnosis or monitoring of suspected drug-associated valvular heart disease.[187] It seems prudent to perform echocardiography in all patients who have received therapy with fenfluramine, dexfenfluramine, pergolide, or cabergoline. Routine follow-up echocardiography is not recommended for patients classified as having trivial disease or in those without valvular abnormalities on the initial echocardiogram.[187] Either transthoracic or transesophageal echocardiography may be used for initial diagnosis and serial evaluations for patients with suspected drug-induced valvulopathy.[189] Symptomatic severe valvular regurgitation may necessitate valve replacement or repair based on standard criteria.[187] Heart failure symptoms should be treated with diuretics and vasodilators. Patients with valvular heart disease due to drug therapy should receive antimicrobial prophylaxis against endocarditis before undergoing invasive procedures with the potential to result in bacteremia.[187]

Table 29-7 Treatment Options for Management of Drug-Induced Valvular and Pericardial Heart Disease

Management of valvular heart disease

- Administer antimicrobial prophylaxis against endocarditis before invasive procedures
- Discontinue therapy with the offending agent
- Obtain baseline and serial echocardiograms
- Treat heart failure symptoms with diuretics and vasodilators
- Valve replacement or repair for severe symptomatic disease

Management of pericarditis

- Bed rest
- Corticosteroids for patients with drug-induced SLE-like syndrome
- Discontinue the offending agent
- Management of large pericardial effusion or hemopericardium and cardiac tamponade

- NSAID and/or colchicine with supplemental narcotic analgesia if needed
- Pericardiocentesis
- Surgical pericardectomy for severe constrictive pericarditis
- Surgical pericardiotomy

Management of large pericardial effusion or hemopericardium and cardiac tamponade

- Discontinue therapy with the offending agent
- Pericardiocentesis
- Surgical pericardiotomy

NSAID = nonsteroidal anti-inflammatory drug, SLE = systemic lupus erythematosus.

Patients with pericarditis should be placed on bed rest, receive nonsteroidal anti-inflammatory drugs (e.g., aspirin, ibuprofen, or colchicine), and, in severe cases of SLE-associated pericardial disease, should receive therapy with systemic corticosteroids.[2] Colchicine is used for recurrent or persistent pericarditis and has also been used for acute pericarditis associated with cancer chemotherapy.[188,193] Surgical pericardectomy may be required for constrictive pericarditis.[179] Patients with cardiac tamponade and some patients with large pericardial effusion or hemopericardium require pericardiocentesis or surgical pericardiotomy.[2]

INFORMATION FOR PATIENTS

Patients taking drugs known to cause valvular or pericardial heart disease should be instructed to report symptoms of heart failure to their healthcare provider. Patients taking drugs associated with pericarditis should be directed to immediately report symptoms of dyspnea, chest pain, or peripheral edema. Those taking agents associated with drug-induced SLE-like syndrome should be advised of the symptoms of this condition. All patients exposed to drugs associated with valvular or pericardial disease should be screened carefully, and appropriate diagnostic testing should be initiated if any abnormalities are detected by history, physical exam, or ECG.

CHAPTER 30

Glucose and Insulin Dysregulation

Devra K. Dang, Frank Pucino, Jr., Charles D. Ponte, and Karim Anton Calis

Glucose homeostasis is regulated by the complex interplay of insulin, hepatic glucose production, peripheral glucose utilization, and counterregulatory mechanisms. Insulin is secreted by pancreatic β cells in response to an increase in plasma glucose concentration and promotes glucose uptake by the liver, muscle, and adipose tissue. Insulin stimulates glycogen synthesis, lipogenesis, and protein synthesis and inhibits lipolysis and hepatic gluconeogenesis. In healthy individuals, a normal plasma glucose concentration is needed to maintain physiological function and meet the energy needs of the brain and various tissues. Insulin secretion is reduced as plasma glucose concentrations decline. When plasma glucose concentrations decrease below the physiological range, counterregulatory hormones are secreted, including glucagon, adrenaline (epinephrine), growth hormone, and cortisol. These hormones restore plasma glucose concentrations to the physiological range through various effects, including stimulation of gluconeogenesis and glycogenolysis, inhibition of insulin secretion and peripheral glucose utilization, and stimulation of lipolysis. Hyperglycemia and hypoglycemia both result from an imbalance between plasma glucose and insulin concentration. Drugs may induce hyper- or hypoglycemia through a variety of mechanisms, including alterations of insulin secretion and sensitivity, changes in gluconeogenesis, and direct cytotoxic effects on pancreatic β cells. Drug-induced hyper- or hypoglycemia can lead to significant consequences, including diabetes mellitus, severe hypoglycemia, coma, and death. However, these events can be prevented and/or minimized with awareness of the problem, close monitoring, and judicious use of the suspect drug(s).

CAUSATIVE AGENTS

Table 30-1 and **Table 30-2** list the medications that have been associated with hyperglycemia and hypoglycemia, respectively. Although sporadic reports of glucose and insulin dysregulation associated with many drugs appear in the literature, only those drugs reported to cause these diseases in one or more clinical trials or observational studies or in multiple case reports will be discussed in this chapter. Glucocorticoids, protease inhibitors, atypical antipsychotics, niacin, pentamidine, and diazoxide are among the agents that have been consistently associated with hyperglycemia and diabetes mellitus. Agents commonly implicated in drug-induced hypoglycemia include insulin, sulfonylureas, and ethanol alone or taken concomitantly. These agents accounted for more than 70% of 1418 cases of severe hypoglycemia in a report spanning the years 1940–1989.[1] In children 2 years of age or younger, salicylate poisoning was reported to cause the majority of cases of drug-induced hypoglycemia.[1]

Table 30-1 Agents Implicated in Drug-Induced Hyperglycemia

Drug or Drug Class	Incidence[a]	Level of Evidence[b]
Antidepressants[34,35,c]	Variable	B
Atypical antipsychotics[4,15,36-42]	NK Highest incidence with olanzapine and clozapine	B
β-adrenergic receptor blockers[43-46]	NK Incidence higher with nonselective β blockers Vasodilating β blockers (carvedilol, nebivolol, and labetalol) do not affect glycemic control	B
Calcium channel blockers[47-50]	Rare (most reports with high doses of diltiazem and verapamil; a few case reports with nifedipine)	C
Chlorpromazine[51,52]	NK	C
Cyclosporine[53-56]	New-onset PTDM: 4–11% in kidney transplant patients	B
Diazoxide[57-60]	NK	B

Thiazide and thiazide-like diuretics[10,22,61-66]	NK Incidence is lower with doses <25 mg of HCTZ equivalent	A
Fish oil[67-71,d]	NK	B
HMG CoA reductase inhibitors[28,30,72,73,e]	Variable	A
Glucocorticoids[9,10,74-81]	<1–46% for new-onset diabetes Incidence varies depending on dose, duration, and route of administration Lower incidence with inhaled formulations	A
Gonadotropin-releasing hormone agonists[82-84]	<5%–10.9%	B
Recombinant human growth hormone[54,85,86]	NK	C
Interferons[87-89]	NK	C
l-asparaginase[54,90-95]	NK	B
Mammalian target of rapamycin (mTOR) inhibitors[96-99]	13–55% with everolimus, 18–22% with sirolimus, 26% with temsirolimus Data for sirolimus are with concomitant administration with cyclosporine, mycophenolate tacrolimus, or azathioprine	A
Megestrol acetate[54,100-106]	NK	B
Niacin (nicotinic acid)[54,107-109]	NK	A
Nucleoside reverse transcriptase inhibitors[54,110-119]	NK More commonly associated with stavudine, zidovudine, and didanosine	B
Oral contraceptives[120-124]	NK More common with formulations containing high-dose estrogen (>35 mcg ethinyl estradiol or equivalent) or second-generation progestin	B
Pentamidine[125-132]	NK	B
Phenytoin[133-136]	Rare	B
Protease inhibitors [32,137-144]	5% for new-onset diabetes mellitus; up to 40% for impaired glucose tolerance	B
Rifampin[145]	NK	B
Ritodrine[146-148]	NK	C
Somatostatin analogs[149-152]	14% with lanreotide; 40% pasireotide; 16–27% with octreotide For octreotide: 16% in acromegaly patients, 27% in carcinoid patients with the depot version	A
Tacrolimus[56,153-157]	Variable	A

	New-onset insulin-dependent PTDM: 20% (kidney transplant patients), 11–18% (liver transplant patients) Hyperglycemia: 22% (kidney transplant patients), 33–47% (liver transplant patients) Patients received concomitant corticosteroid therapy Lower incidence 1 year post-transplant Higher incidence with tacrolimus than with cyclosporine	
Terbutaline[158-160]	NK	A
Thalidomide[161,162]	NK	B
Tyrosine kinase inhibitors[99,163-174]	36% with alectinib, 28% with axitinib, 37% with cabozantinib, 49% with ceritinib, 13–57% with dabrafenib, 9.8% with imatinib, NK for lenvatinib, 50% with nilotinib, 41% with pazopanib, 58% with ponatinib, 23–71% with sunitinib, 27–65% with trametinib (combination therapy with dabrafenib) Has not been reported for all agents within the drug class	A

HCTZ = hydrochlorothiazide, HMG CoA = 3-hydroxy-3-methylglutaryl-coenzyme A, NK = not known, PTDM = post-transplant diabetes mellitus.

[a] Incidence may be related to drug dose.

[b] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[c] Controversial: data mostly from observational studies, with some showing no association with hyperglycemia/diabetes. Many studies did not differentiate between antidepressant drug classes and those that did found differing results. Association with diabetes confounded by concomitant depression.

[d] Usually only occurs in patients with impaired glucose tolerance or diabetes mellitus. Risk is usually associated with doses >3 g/day. A 2008 Cochrane meta-analysis concluded that there were no significant changes in fasting glucose or hemoglobin A1C in randomized, placebo-controlled trials conducted in patients with type 2 diabetes.[69]

[e] Risk appears to be higher with higher potency statins and doses (highest risk with rosuvastatin). A 2013 meta-analysis calculated that the increased risk for new-onset diabetes, compared with placebo, is 25% with rosuvastatin 20 mg/day, 15% with atorvastatin 80 mg/day, and 7% with pravastatin 40 mg/day.[73]

EPIDEMIOLOGY

The true incidence of glucose and insulin dysregulation associated with most drugs is unknown. This is due, in large part, to a lack of data from controlled clinical trials, underreporting of postmarketing events, and failure to establish causality. For some medications, the incidence of drug-induced hyperglycemia or hypoglycemia may also vary depending on the dose, frequency, and/or duration of drug administration as well as the patient's underlying disease states. For example, in the Diabetes Control and Complications Trial, the incidence of severe hypoglycemia requiring assistance associated with insulin administration was threefold higher in the intensively-treated group (insulin pump or ≥3 daily insulin injections) compared to the conventionally-treated group (1–2 daily insulin injections).[2,3] Within a specific drug class, the incidence of drug-induced hyper- or hypoglycemia also may vary. Hyperglycemia and diabetes mellitus occur more commonly in association with olanzapine and clozapine than with the other atypical antipsychotic drugs.[4,5] However, an increased background risk for diabetes mellitus associated with schizophrenia, in addition to the rising incidence of diabetes in the general population, complicate determination of precise risk estimates. The incidence of treatment-related hyperglycemia also may be higher if the patient has predisposing risk factors for diabetes mellitus, such as obesity or a family history. Hypoglycemia is more common in association with long-acting (e.g., chlorpropamide and glyburide) than shorter-acting sulfonylureas (e.g., tolbutamide).[6,7] The reported incidence of drug-induced hypoglycemia may also vary depending on the specific definition of hypoglycemia used. Additionally, factors such as the presence of active drug metabolites and the presence of other risk factors for hypoglycemia also account for the difference in reported incidences of hypoglycemia among various drugs. Finally, the route of administration and systemic availability of a drug may also influence the incidence of drug-induced hyper- or hypoglycemia. For example, inhalation of corticosteroids or pentamidine infrequently causes alterations in glucose homeostasis compared to administration via the oral or parenteral routes.[8,9]

Table 30-2 Agents Implicated in Drug-Induced Hypoglycemia

Drug or Drug Class	Incidence[a]	Level of Evidence[b]
Angiotensin-converting enzyme inhibitors[24,175-177]	NK	A
β-adrenergic receptor blockers[1,24,44,178-183]	NK, but likely rare Effects more commonly associated with nonselective β blockers	C
Bitter melon (*Momordica charantia*) (also commonly known as karela)[184-190]	NK	B
Dipeptidyl peptidase 4 inhibitors[191]	Rare as monotherapy, increased risk when combined with insulin or insulin secretagogue	A
Disopyramide[192-196]	NK	B
Ethanol[1,24,178,197]	NK	C
Fenugreek (*Trigonella foenum graecum*)[189,198-200]	NK	B[d]

Fluoroquinolones[201-207]	NK	B
Ginseng[189,208-211]	NK	B[c]
Glucagon-like peptide 1 receptor agonists[212]	Up to 15.9% with monotherapy Up to 42% in combination with a sulfonylurea	A
Insulin[2,25,213]	Variable: 2.76–62 episodes per 100 patient-years for severe hypoglycemia requiring assistance Higher incidence in patients with type 1 versus type 2 diabetes.	A
Ivy gourd (*Coccinia indica*)[189,214]	NK	B[c]
L-carnitine[189,215-217]	NK	B
Nonsulfonylurea secretagogues[218-220]	NK; lower incidence compared to sulfonylureas	A
Pentamidine[8,128,129,131,221-223]	6–40% with intravenous or intramuscular formulations, 1% or less with nebulized formulation	B
Pramlintide[224-226,d]	0.6–16.8% Does not cause hypoglycemia when used alone but increases risk of insulin-induced hypoglycemia (can be severe) when combined with insulin Higher incidence in patients with type 1 (5.2–16.8%) versus type 2 (0.4–8.2%) diabetes Incidence is lowered (0.9–5.7%) when the dose of preprandial insulin is decreased by 50% when initiating pramlintide	A
Quinine[178,227-232]	NK	B
Quinidine[178,227,233]	NK	B
Salicylates[1,18,178,234]	NK More common in children compared to adults Most common cause of severe hypoglycemia in children ≤2 years	B
Sodium-glucose cotransporter 2 inhibitors[235-237]	Low as monotherapy, increased risk when combined with insulin or insulin secretagogue	A
Somatostatin analogs[149-152]	9% in a study with pasireotide 2–4% with octreotide	A
Sulfamethoxazole[238-242]	NK Rare reaction with kidney disease and/or high doses	C
Sulfonylureas[1,6,213,243,e]	Variable 1.8% per year for recorded hypoglycemia, 1.23 per 100 person-years or 3.3% for severe hypoglycemia requiring medical attention	A
Tyrosine kinase	Lenvatinib >5%, 2–10% with sunitinib, 17% with pazopanib, 24% with ponatinib, 24% with	A (lenvatinib, nilotinib,

inhibitors[99,165,166,172,173,244,245]	vandetanib Reported but incidence not known with dasatinib, imatinib, nilotinib, and sorafenib Has not been reported for all agents within the drug class	pazopanib, sunitinib, vandetanib) C (dasatinib, imatinib, and sorafenib)

NK = not known.

[a] Incidence may be related to drug dose.

[b] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[c] Even though there are one or more randomized, controlled clinical trials demonstrating the glucose-lowering effect of this herbal agent, a B rating for level of evidence is given because the overall effect is inconclusive.

[d] Severe hypoglycemia, if occurs, onset is usually within 2–3 hours after administration of pramlintide.

[e] Higher incidence reported with chlorpropamide and glyburide.

MECHANISMS

Drugs can induce hyper- or hypoglycemia through multiple mechanisms, including alteration of insulin secretion or clearance, changes in insulin sensitivity (either directly at the receptor level or by indirect effects on weight or adiposity), changes in gluconeogenesis or glucose metabolism, and direct cytotoxic effects on pancreatic β cells. Mechanisms by which specific drugs are believed to alter glucose or insulin regulation are listed in **Table 30-3** and **Table 30-4**. With some medications, it is not clear if hyperglycemia is a direct effect of the drug itself or if the drug is simply a contributing factor, as occurs in cases when a drug unmasks a patient's pre-existing diabetes.[10]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The signs and symptoms of drug-induced hyperglycemia and diabetes mellitus are listed in **Table 30-5**. The diagnosis of diabetes mellitus can be made if a patient's glycosylated hemoglobin (A1C) is ≥6.5%, the fasting plasma glucose concentration is ≥126 mg/dL, or the patient is found to have a plasma glucose concentration of ≥200 mg/dL 2 hours after a 75-g oral glucose load. A positive result on any of these tests should be confirmed on a separate occasion unless there is unequivocal hyperglycemia. A diagnosis can also be made if the patient has classic symptoms of diabetes and a random plasma glucose concentration of ≥200 mg/dL.[11] Depending on the causative agent, drug-induced hyperglycemia can appear within hours or weeks to months after initiation of therapy. Hyperglycemia may be severe in some cases, manifesting as diabetic ketoacidosis and hyperglycemic coma.

Table 30-3 Mechanisms of Drug-Induced Hyperglycemia[4,9,10,15,22,28,30,34-174]

Drug or Drug Class	Proposed Mechanism(s)
Antidepressants	Weight gain, ↑ cortisol, inhibits insulin signaling, inhibits insulin secretion, ↑ gluconeogenesis and glycogenolysis
Atypical antipsychotics	↓ peripheral insulin sensitivity, ↓ insulin secretion (inhibition of β-cell responsiveness via antagonism of the 5-HT$_{1A}$ receptor), promote weight gain; may also cause hyperglycemia through drug-induced pancreatitis
β-adrenergic receptor blockers	↓ insulin secretion, ↓ insulin sensitivity; effects attenuated but not abolished with cardioselective β blockers
Calcium channel blockers[48]	↓ insulin secretion
Cyclosporine	↓ insulin production, inhibits insulin secretion, ↓ β-cell volume and function, ↑ insulin resistance
Diazoxide	↓ insulin secretion, may also ↑ glucose production and ↓ insulin sensitivity
Fish oil	Unknown
HMG CoA reductase inhibitors	↑ insulin resistance, ↓ insulin secretion
Glucocorticoids[79]	↑ gluconeogenesis, ↑ insulin resistance, ↓ insulin secretion
Gonadotropin-releasing hormone agonists	↓ testosterone concentrations leading to ↑ fat mass and ↑ insulin resistance
Growth hormone	Causes insulin resistance
Interferons	Formation of islet cell antibodies
l-asparaginase	↓ insulin synthesis
Mammalian target of rapamycin (mTOR) inhibitors	↑ insulin resistance, ↑ gluconeogenesis, chronic administration leads to pancreatic β-cell apoptosis
Megestrol acetate	↓ insulin sensitivity and promotes weight gain; binds to glucocorticoid receptor
Niacin (nicotinic acid)	↓ insulin sensitivity, ↑ hepatic gluconeogenesis
Nucleoside reverse transcriptase inhibitors	↑ insulin resistance, promote lipodystrophy; can also cause pancreatitis (more common with didanosine and stavudine) leading to β-cell injury; didanosine postulated to inhibit insulin release secondary to hypokalemia
Oral contraceptives	Estrogen-induced ↓ peripheral insulin sensitivity
Pentamidine	Direct cytolytic effects on pancreatic β cells; causes hypoglycemia initially; effect may be irreversible; can also cause pancreatitis
Phenytoin	↓ insulin secretion, may also ↓ insulin sensitivity
Protease inhibitors	↑ insulin resistance directly or indirectly, promote lipodystrophy, ↓ insulin secretion
Recombinant human growth	Causes insulin resistance

hormone	
Rifampin	Unknown, may ↑ intestinal absorption of glucose
Ritodrine	↑ hepatic gluconeogenesis
Somatostatin analogs	Inhibits secretion of insulin; pasireotide also ↓ GLP-1 and GIP
Tacrolimus	↓ insulin secretion, ↓ insulin sensitivity; may cause pancreatic islet cell toxicity; hyperglycemia and diabetes mellitus reported without use of concomitant corticosteroids
Terbutaline	↑ gluconeogenesis and glycogenolysis, ↓ peripheral insulin sensitivity
Thalidomide	↓ insulin-stimulated glucose uptake and glycogen synthesis
Thiazide and thiazide-like diuretics	↓ insulin release secondary to hypokalemia (hyperglycemia may be preventable through correction/prevention of hypokalemia); other mechanisms, including a direct inhibition of insulin release, ↓ insulin sensitivity, ↑ hepatic gluconeogenesis, a direct toxic effect on pancreatic β cells from increased free fatty acids, and increased sympathetic nervous system activity (contributing to hypokalemia) have also been proposed
Tyrosine kinase inhibitors	↑ insulin resistance, inhibits glycogen synthesis, activates glycogenolysis

↑ = increases, ↓ = decreases, GLP-1 = glucagon-like peptide-1, GIP = glucose-dependent insulinotropic polypeptide, HMG CoA = 3-hydroxy-3-methylglutaryl-coenzyme A, HT = hydroxytryptamine.

Table 30-4 Mechanisms of Drug-Induced Hypoglycemia[1,2,8,18,24,25,44,99,129,131,175-245]

Drug or Drug Class	Proposed Mechanism(s)
Angiotensin-converting enzyme inhibitors[177]	↑ peripheral insulin sensitivity
β-adrenergic receptor blockers	May ↑ peripheral glucose uptake and indirectly ↓ gluconeogenesis; can delay recovery from hypoglycemia; also mask many autonomic hypoglycemic symptoms
Bitter melon (*Momordica charantia*) (also commonly known as karela)	Proposed: components of extracts structurally similar to animal insulin, ↑ insulin secretion, ↑ tissue glucose uptake, ↑ hepatic glycogen synthesis, ↑ peripheral glucose oxidation in erythrocytes and adipocytes, ↓ hepatic gluconeogenesis
Dipeptidyl peptidase-4 inhibitors	Inhibit degradation of the incretin hormones GIP and GLP-1, which ↑ glucose-dependent insulin synthesis and release; GLP-1 also ↓ glucagon secretion from alpha cells in the pancreas
Disopyramide[194,196]	↑ insulin secretion
Ethanol	Inhibits hepatic gluconeogenesis, impairs activation of the HPA axis' hormonal response to hypoglycemia, and can potentiate hypoglycemic effects of other drugs; more problematic when glycogen stores are low
Fenugreek (*Trigonella foenum graecum*)	Proposed: slows carbohydrate absorption, inhibits glucose transport
Fluoroquinolones[204,207]	Unknown, may be due to stimulation of pancreatic insulin secretion and/or interaction with antidiabetic agents; most reports with gatifloxacin; resistant

	hypoglycemia (resolves with discontinuation only) may occur
Ginseng	Proposed: ↓ rate of carbohydrate absorption into portal hepatic circulation, ↑ glucose transport and uptake mediated by nitric oxide, ↑ glycogen storage, modulation of insulin secretion; most clinical trials done using American ginseng (*Panax quiquefoliu*)
Glucagon-like peptide 1 receptor agonists	Stimulates glucose-dependent insulin release, suppresses glucagon secretion
Insulin	↑ glucose utilization
Ivy gourd (*Coccinia indica*)	Insulin-mimetic
L-carnitine[215-217]	↑ glucose uptake and storage
Nonsulfonylurea secretagogues	↑ pancreatic insulin secretion
Pentamidine[131]	↑ insulin release through direct cytotoxic effects to pancreatic β cells
Pramlintide	Suppresses postprandial glucagon secretion, slows gastric emptying
Quinine	↑ pancreatic insulin secretion, usually with high doses or rapid IV infusion; *Plasmodium falciparum* infection itself is associated with hypoglycemia
Quinidine	↑ pancreatic insulin secretion; see quinine
Salicylates[18]	↑ pancreatic insulin secretion, ↑ peripheral glucose utilization, ↓ gluconeogenesis; usually occurs only with anti-inflammatory doses
Sodium-glucose cotransporter 2 inhibitors	Inhibits renal reabsorption of filtered glucose leading to increased urinary glucose excretion
Somatostatin analogs	Inhibits secretion of glucagon
Sulfamethoxazole	↑ pancreatic insulin secretion
Sulfonylureas	↑ pancreatic insulin secretion
Tyrosine kinase inhibitors	Unknown

↑ = increases, ↓ = decreases, GIP = glucose-dependent insulinotropic polypeptide (GIP), GLP-1 = glucagon-like peptide-1, HPA = hypothalamic-pituitary-adrenal, IV = intravenous, NK = not known.

Although there is considerable interindividual variation, the typical signs and symptoms associated with hypoglycemia are presented in **Table 30-6**. The glycemic threshold at which patients experience hypoglycemic symptoms varies. Symptoms commonly manifest when the plasma glucose concentration falls below 60 mg/dL. However, factors such as prolonged hyperglycemia, caffeine use, or frequent episodes of hypoglycemia may shift this threshold in either direction. Patients who experience repeated episodes of hypoglycemia over a short period of time may become unaware of these events. These patients do not experience typical hypoglycemic symptoms and may fail to take corrective action as a result of central nervous system impairment.[12] Severe hypoglycemia can lead to cognitive dysfunction, mental status changes, seizures, coma, or even death.

Table 30-5 Signs and Symptoms Associated with Drug-Induced Hyperglycemia

Mild-to-moderate hyperglycemia

- Blurred vision
- Fatigue/weakness
- Polydipsia
- Polyphagia
- Polyuria
- Unexplained weight loss

Severe hyperglycemia

- Abdominal pain
- Coma
- Dehydration
- Hypokalemia
- Hypotension
- Kussmaul respiration and breath with fruity odor
- Lethargy
- Metabolic acidosis
- Muscle cramping
- Nausea and vomiting
- Obtundation

Table 30-6 Signs and Symptoms Associated with Drug-Induced Hypoglycemia

Mild-to-moderate hypoglycemia

- Dizziness
- Headache
- Hunger
- Shakiness/tremors
- Sweating/diaphoresis
- Tachycardia
- Weakness/fatigue

Severe hypoglycemia

- Behavioral changes such as anxiety and irritability
- Blurred vision
- Coma
- Confusion and difficulty concentrating
- Loss of consciousness
- Seizure

Before implicating a drug as the cause of glucose or insulin dysregulation, other possible etiologies must be ruled out (**Table 30-7**). Hyperglycemia may occur during periods of physiologic stress such as surgery, infection, or trauma. Elevations in serum glucose concentrations associated with Cushing syndrome may result either from exogenous administration or endogenous overproduction of glucocorticoids. When assessing possible causes of hypoglycemia, intentional self-administration of hypoglycemic drugs, usually insulin or a sulfonylurea (i.e., factitious hypoglycemia), and iatrogenic causes (including medication dispensing errors) should be considered.[13] Hypoglycemia also occurs in patients with acute illness. Uncommon causes of hypoglycemia include insulin-producing tumors (e.g., an insulinoma) and several other rare disorders (**Table 30-7**). To adequately assess drug-induced causality, it is important to consider such variables as temporal sequence, biologic plausibility, and whether hyper- or hypoglycemia is a known class or drug effect in the absence of other potential confounders (e.g., concomitant diseases or medications).

Table 30-7 Conditions to Consider in the Differential Diagnoses of Drug-Induced Glucose and Insulin Dysregulation

Differential diagnoses for drug-induced hyperglycemia

- Acromegaly
- Cushing syndrome
- Diabetes mellitus
- Kidney disease
- Liver cirrhosis
- Metabolic acidosis
- Metabolic syndrome
- Pancreatitis
- Parenteral nutrition therapy (dextrose administration)
- Stress hyperglycemia

Differential diagnoses for drug-induced hypoglycemia[33,246]

- Acute kidney injury or chronic kidney disease
- Adrenal insufficiency (e.g., Addison disease, adrenal crisis)
- Alcoholism
- Beckwith-Wiedemann syndrome
- Carnitine deficiency
- Congenital hyperinsulinemic hypoglycemia of infancy
- Defective type 1 glucose transporter in the brain
- Erythroblastosis fetalis
- Factitious or iatrogenic hypoglycemia
- Galactosemia
- Glycogen storage disease
- Heart failure
- Hepatic failure
- Hereditary fructose intolerance
- Hypopituitarism
- Insulin-binding antibodies disorder
- Insulinoma
- Isolated adrenocorticotropic hormone deficiency
- Isolated growth hormone deficiency

- Lactic acidosis
- Large non- β-cell tumor
- Noninsulinoma pancreatogenous hypoglycemia syndrome
- Pancreatic islet cell hyperplasia/nesidioblastosis
- Persistent hyperinsulinemic hypoglycemia of infancy
- Postoperative following removal of pheochromocytoma
- Pseudohypoglycemia (i.e., in vitro glycolysis resulting in artifactually low glucose concentrations as observed with leukemias, polycythemia and hemolytic anemia)
- Reye syndrome
- Roux-en-Y gastric bypass (leading to pancreatic islet nesidioblastosis or insulinoma)
- Sepsis
- Small size for gestational age infants

Table 30-8 Risk Factors for Drug-Induced Hyperglycemia

- Patients with underlying risk factors for type 2 diabetes mellitus[11]
    - o Age ≥45 years
    - o Diagnosis of prediabetes (as per hemoglobin A1C, impaired fasting glucose, or impaired glucose tolerance)
    - o First-degree relative with diabetes
    - o High-density lipoprotein cholesterol <35 mg/dL (0.90 mmol/L) and/or a triglyceride concentration >250 mg/dL (2.82 mmol/L)
    - o History of gestational diabetes mellitus
    - o History of cardiovascular disease
    - o Hypertension (≥140/90 mm Hg or on treatment for hypertension)
    - o Other clinical conditions associated with insulin resistance such as severe obesity or acanthosis nigricans
    - o Overweight (BMI ≥25 kg/m^2 or BMI ≥23 kg/m^2 in Asian Americans)
    - o Physical inactivity
    - o Polycystic ovary syndrome
    - o Race/ethnicity (e.g., African-American, Latino, Native American, Asian-American, and Pacific Islander)
- Higher doses (e.g., thiazide diuretics or corticosteroids) or misuse of suspected drug
- Concomitant use of more than one drug that can induce hyperglycemia
- Drug interactions (use of drugs that may increase the plasma concentration and/or hyperglycemic effect of offending drug)

BMI = body mass index.

RISK FACTORS

Risk factors for drug-induced hyperglycemia and hypoglycemia are listed in **Table 30-8** and **Table 30-9**, respectively. Patients with type 2 diabetes mellitus or those predisposed to it (e.g., individuals with metabolic syndrome) may be at particular risk for drug-induced hyperglycemia due to worsening of pre-existing insulin resistance and β cell dysfunction. Patients with other underlying disease states also may be at increased risk. For example, hypertension and schizophrenia are associated with a higher incidence of diabetes mellitus and therefore may confound the diagnosis of drug-induced hyperglycemia.[14,15] Polymedication is another important risk factor, because the concomitant use of multiple medications associated with glucose or insulin dysregulation may lead to additive pharmacokinetic and/or pharmacodynamic effects. For example, the combined use of sulfonylureas and nonsteroidal anti-inflammatory drugs, including ibuprofen and aspirin, may lead to an increased risk of hypoglycemia due in part to decreased sulfonylurea metabolism or increased insulin release.[16-18]

Table 30-9 Risk Factors for Drug-Induced Hypoglycemia

- Advanced age
- Concomitant use of more than one drug that can induce hypoglycemia
- Decreased carbohydrate intake (e.g., overnight fast, missed meals)
- Hepatic dysfunction (decreased gluconeogenesis)
- Higher doses or misuse of offending drug
- History of hypoglycemia
- Hospitalization within past 30 days
- Increased carbohydrate utilization (e.g., exercise) or reduced stores (e.g., malnutrition)
- Pharmacodynamic or pharmacokinetic interactions (e.g., increased response and/or plasma concentration of suspected drug)
- Recent or excessive alcohol intake
- Renal dysfunction (decreased insulin clearance)
- Tight glycemic control in patients with diabetes

MORBIDITY AND MORTALITY

Drug-induced hyperglycemia may be transient or may result in permanent changes in glucose regulation. Similar to other causes of diabetes mellitus, drug-induced hyperglycemia is believed to increase the risk of microvascular (retinopathy, neuropathy, and nephropathy) and macrovascular (atherosclerotic cardiovascular disease, cerebrovascular disease, and peripheral vascular disease) complications, delayed wound healing and resolution of infections, hyperosmolar coma, and death. Cases of diabetic ketoacidosis and death have been reported in association with many of the drugs listed in Table 30-1. Diabetic nephropathy, sensorimotor peripheral neuropathy, ketoacidosis, hyperosmolar coma or precoma, myocardial infarction, and stroke were reported in a cohort of kidney transplant recipients (followed on average for 9.3 years) who developed post-transplant diabetes mellitus. The immunosuppressive regimen prescribed for these patients consisted of cyclosporine and corticosteroids, which are known to be associated with hyperglycemia.[19] New-onset diabetes after transplantation is known to be associated with decreased graft and patient survival, and increased risk of infection and cardiovascular disease.[20,21] However, drug-induced hyperglycemia may not always lead to the development of macrovascular complications. This was evident in the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack

Trial, a large, randomized controlled study of older hypertensive patients with and without metabolic syndrome.[22] Although the incidence of newly-diagnosed diabetes was greater in chlorthalidone-treated patients compared to those treated with either lisinopril or amlodipine, the risk of developing coronary heart disease, stroke, end-stage renal disease, and all-cause mortality did not differ significantly among groups. The systolic blood pressure was 0.8-mm Hg and 2-mm Hg lower in the chlorthalidone group compared to the amlodipine and lisinopril group, respectively.[23]

Although drug-induced hypoglycemia typically produces transient, mild-to-moderate symptoms, some patients may experience discomfort and reduced quality of life and consequently discontinue treatment due to fear of recurrent episodes. Severe hypoglycemic episodes can lead to mental status changes, seizures, loss of consciousness, permanent neurological damage, and death. Sulfonylurea-induced hypoglycemia has resulted in permanent neurological deficits in 5% of survivors and has a reported mortality rate of 10%. Furthermore, insulin-induced hypoglycemia may be responsible for approximately 2–4% of deaths reported in patients with type 1 diabetes.[24,25]

In addition to substantial morbidity and mortality, drug-induced glucose and insulin dysregulation also carries a significant economic burden. Hospitalizations and urgent care visits related to drug-induced hyper- or hypoglycemia can substantially increase healthcare costs.[26,27] Healthcare expenditures include not only direct treatment costs, but also costs associated with the investigations required to rule out nondrug-related etiologies.

Relative risks and benefits of administering medications known to cause hyper- or hypoglycemia must be weighed. For example, a meta-analysis calculated that the use of 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase inhibitors (also known as statins) may cause one new case of diabetes for every 255 patients treated for 4 years. However, 5.4 major coronary events (coronary heart disease death and nonfatal myocardial infarction) are prevented.[28] Statin therapy is recommended in patients with diabetes by both the 2017 American Diabetes Association's *Standards of Medical Care in Diabetes* guideline and the 2017 American Association of Clinical Endocrinologists and American College of Endocrinology's *Comprehensive Type 2 Diabetes Management Algorithm* to prevent atherosclerotic cardiovascular disease (ASCVD).[11,29] For patients with prediabetes, both guidelines only provide a general recommendation that the same treatment recommendations for the general population to prevent ASCVD also apply to these patients.[11,29] The Justification for the Use of Statins in Prevention: an Intervention Trial Evaluating Rosuvastatin investigated the effects of rosuvastatin 20 mg daily on the development of first major cardiovascular events. An exclusion criterion at study entry was diagnosed diabetes. The authors calculated that in patients with one or more major diabetes risk factors, for every 54 new cases of diabetes, 134 total cardiovascular events or deaths were avoided. In patients without a major diabetes risk factor, no new case of diabetes was diagnosed, and 86 total cardiovascular events or deaths were avoided.[30]

PREVENTION

Approaches for preventing drug-induced glycemic changes are listed in **Table 30-10**. Although not always possible, avoiding potentially causative drugs in high-risk patients is the best preventive strategy. The relative risks and benefits of drug therapy must be considered on a case-by-case basis. Close monitoring for signs and symptoms of abnormalities in blood glucose concentrations is essential for patients receiving drugs that may alter glucose or insulin regulation. Healthcare professionals should always inquire about their patients' use of nonprescription medications and dietary supplements, as some of these have been linked to changes in glycemic control (Tables 30-1 and 30-2). Depending on risk assessment, blood glucose concentrations should be obtained before initiating therapy with drugs known to cause glucose or insulin dysregulation and periodically thereafter. The frequency of blood glucose monitoring should be dependent upon several factors including the patient's risk for, or overt manifestations of, hypo- or hyperglycemia, provider assessment, and the availability of published guidelines from drug manufacturers or other sources. Monitoring for changes in blood glucose concentrations and clinical manifestations of hypo- or hyperglycemia also is recommended following discontinuation of medications known to induce glucose and/or insulin dysregulation.

Table 30-10 Approaches to Help Prevent Drug-Induced Glucose and Insulin Dysregulation

- Avoid or minimize concomitant administration of drugs that may have pharmacokinetic or pharmacodynamic drug interactions with potentially causative drug
- Avoid or minimize concomitant administration of more than one drug that can induce glucose and/or insulin dysregulation
- Inquire about symptoms of hyperglycemia and hypoglycemia at each office visit
- Monitor fasting plasma glucose concentration within the first few weeks after initiating high-risk drugs and regularly thereafter, especially in the presence of weight changes or pre-existing disorders of glucose metabolism; for patients taking glucocorticoids, consider also monitoring postprandial plasma glucose concentration, given the onset of action of prednisone
- Monitor weight at each office visit
- Obtain baseline fasting plasma glucose concentration prior to initiation of potentially causative drugs, particularly in patients with risk factors
- Use lowest effective dose for the shortest duration of administration if possible

MANAGEMENT

Strategies for managing drug-induced glucose and insulin dysregulation are presented in **Table 30-11**. Although discontinuation of therapy with the offending agent usually reverses the drug-induced hypo- or hyperglycemia, this strategy may not always be possible. It may not be feasible to discontinue therapy with protease inhibitors, atypical antipsychotics, or tacrolimus, for example. In some of these cases, modifying therapy to a drug less likely to affect blood glucose can be considered. For example, Spivak et al. reported a case of olanzapine-induced diabetes mellitus that resolved after therapeutic substitution with ziprasidone.[31] Also, short-term improvements in insulin resistance have been reported when a non-nucleoside reverse transcriptase inhibitor or abacavir were substituted for a protease inhibitor in patients infected with human immunodeficiency virus-1.[32]

Table 30-11 Management of Drug-Induced Glucose and Insulin Dysregulation

Hyperglycemia

- Administer antidiabetic medications if patient develops diabetes mellitus
- Assess glycemic control (e.g., home blood glucose monitoring, hemoglobin A1C) as appropriate
- Discontinue or reduce dose of offending drug if possible
- Implement appropriate dietary and lifestyle changes, including increased physical activity
- Use offending drug for shortest duration possible at the lowest effective dose

Hypoglycemia

- Administer treatment to reverse hypoglycemia as appropriate (e.g., glucose, dextrose, glucagon, diazoxide)
- Assess glycemic control (e.g., fasting plasma glucose concentration) as appropriate
- Discontinue or reduce dose of offending drug if possible
- Implement dietary changes (e.g., frequent, small meals)
- Use offending drug for shortest duration possible at the lowest effective dose

The time required for improvement of signs and symptoms and/or return to baseline of glycemic status following discontinuation of the causative drug depends on its pharmacokinetic and/or pharmacodynamic properties. In most cases, drug-induced hyperglycemia is reversible within days, but recovery may take longer with drugs such as atypical antipsychotics, protease inhibitors, or corticosteroids that cause hyperglycemia via weight gain or peripheral insulin resistance. In some cases, the effects may be irreversible (e.g., pentamidine-induced destruction of pancreatic β cells). For agents that exhibit a dose-dependent effect on plasma glucose concentrations (e.g., corticosteroids), reducing the dose may ameliorate or reverse the drug-induced disease.

Approaches specific to the management of drug-induced glucose abnormalities have not been studied systematically and patients with drug-induced hyper- or hypoglycemia are typically managed similarly to those with diabetes or hypoglycemia, by following accepted clinical practice guidelines and/or recommendations for these conditions.[11,25,33] Patients with pre-existing diabetes may require an adjustment to their antidiabetic medications to compensate for drug-induced changes in glycemic control. Initiation or discontinuation of therapy with antidiabetic agents also may be required.

INFORMATION FOR PATIENTS

Patients receiving medications known to cause hypoglycemia or hyperglycemia should be educated regarding the associated signs and symptoms, the importance of follow-up testing, and the need for careful management and close medical supervision. Those who already have a diagnosis of diabetes should be informed that they may need to monitor their blood glucose concentrations more frequently and may require adjustments to their antidiabetic regimen. Patients should be educated about the risks and benefits of using medications known to induce glucose or insulin dysregulation and should be counseled to discontinue a potentially causative medication only under medical supervision. Patients should be further advised to inform each of their healthcare professionals about all medication use, including nonprescription medications and dietary supplements.

CHAPTER 31

Thyroid Diseases

Genevieve Lynn Ness, Judy T. Chen, Betty J. Dong, Frank Pucino, Jr., and Karim Anton Calis

The thyroid gland affects virtually every organ system. Thyroid hormones regulate the metabolic rate and affect the growth and function of systems throughout the body. Many drugs, including those used to treat nonthyroid disorders, may affect thyroid function. Drug-induced thyroid disorders occur as a result of changes in thyroid hormone synthesis, transport, metabolism, secretion, or function (**Figure 31-1**).[1-3] Thyroid dysfunction may also result from alterations in the synthesis or release of thyroid stimulating hormone (TSH or thyrotropin) from the pituitary gland or dysregulation of thyroid releasing hormone (TRH) at the level of the hypothalamus. The clinical significance of drug-induced thyroid abnormalities ranges from negligible to potentially life-threatening. Medications that have the potential to induce clinically significant thyroid disorders are the focus of this chapter.

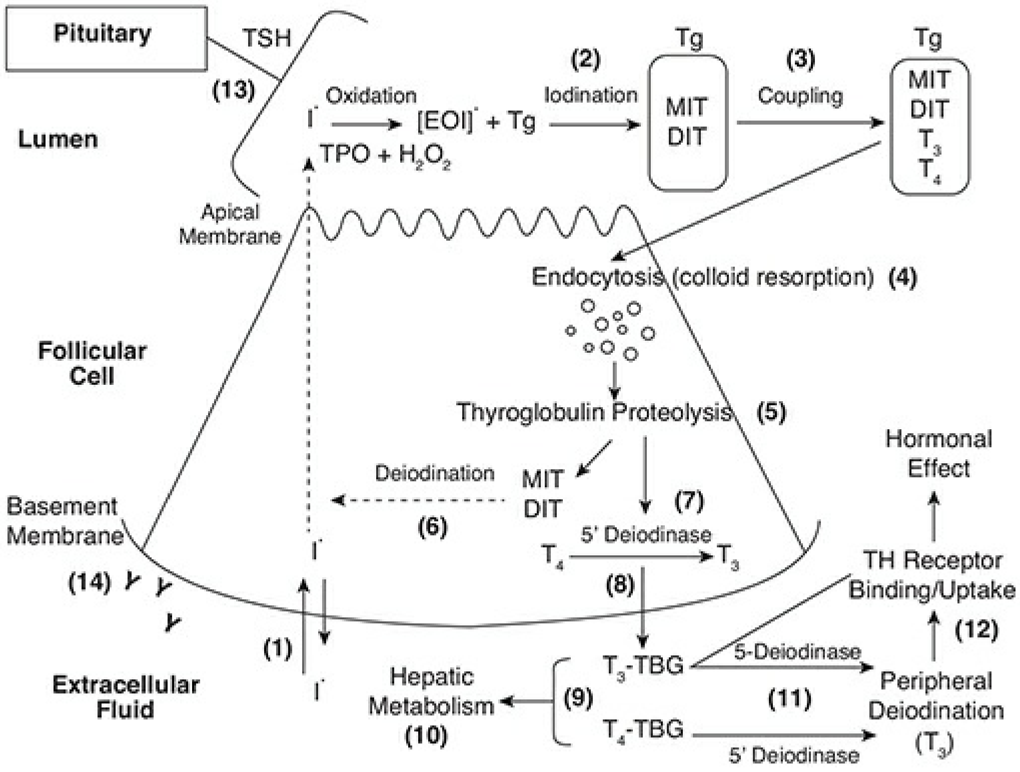

FIGURE 31-1 Steps of Thyroid Hormone Biosynthesis and Secretion and the Sites for Drug-Induced Changes

(1) Iodide is first trapped and actively transported into the follicular cell by a sodium/iodide symporter in the basement membrane. (2) Thyroid peroxidase (TPO) then catalyzes the formation of an active iodinated species [enzyme-bound hypoiodite (EOI)] important for iodination of thyroglobulin (Tg) in the follicular lumen, resulting in the formation of mono-iodotyrosine (MIT) and di-iodotyrosine (DIT). (3) The oxidized form of TPO (compound I) then initiates the coupling reaction, generating liothyronine (T_3) and levothyroxine (T_4) through combining DIT with MIT or DIT, respectively. (4) Tg is then internalized from the lumen by endocytosis. (5) Hormone release occurs after proteolysis in the endosome and lysosome system. (6) Deiodination generates iodide from free MIT and DIT, which is then recirculated, and (7) also results in the formation of T_3 from T_4. (8) Thyroid hormone is subsequently released into the circulation, (9) extensively bound to serum proteins, primarily thyroxine binding globulin (TBG) for transport. It may then undergo (10) hepatic metabolism (glucuronidation, sulfation, deiodination), (11) peripheral deiodination (activation through T_4 conversion to T_3 or inactivation of T_3 and T_4), or (12) bind to thyroid hormone (TH) receptors to elicit a pharmacodynamic response. (13) Release of thyrotropin [thyroid stimulating hormone (TSH)] from the anterior pituitary (adenohypophysis) in response to thyrotropin-releasing hormone (TRH) from the hypothalamus has a stimulatory effect on most steps of iodine metabolism and hormone synthesis and release. Drug and chemical compounds are known to alter the function of each of these steps, result in goiter, and/or (14) initiate an immune reaction resulting in thyroiditis. See Table 31-2[47-61] for a listing of specific drug actions. Adapted with permission from Taurog AM. Hormone synthesis: thyroid iodine metabolism. In: Braverman LE, Utiger RD, eds. *The thyroid: a fundamental and clinical text.* Philadelphia, PA: Lippincott Williams and Wilkins; ©2000:61-85.

Thyroid hormone synthesis is dependent on dietary iodine, which is transported into thyroid follicular cells and incorporated into thyroglobulin via thyroid peroxidases. The process of organification produces mono-iodotyrosines and di-iodotyrosines, which are bound to thyroglobulin. The follicular cells secrete thyroglobulin, which serves as a storage form for thyroid hormone precursors. TSH stimulates iodotyrosines to combine to form thyroxine (T_4) and tri-iodothyronine (T_3) through a process known as coupling. Once released into the circulation, both T_4 and T_3 are highly bound to thyroid-binding globulin and other plasma proteins. Intrinsically, T_3 is more potent than T_4, with approximately 80% of T_3 derived from the peripheral conversion of T_4 by 5'-monodeiodinase.

CAUSATIVE AGENTS

Medications have the potential to induce hypothyroidism, hyperthyroidism, and goiter. Agents most commonly associated with drug-induced thyroid disorders are listed in **Table 31-1**.[4-45] Causality has been assessed for drugs included in this table.[46] Each of these agents has been implicated as the cause of drug-induced thyroid disease in at least one published case report in which a patient exhibited signs or symptoms of disease in addition to any laboratory abnormalities that may have been present. Some agents alter thyroid function tests without causing substantial clinical effects (i.e., they may cause subclinical hypothyroidism or hyperthyroidism). For example, subclinical hypothyroidism is an elevated serum TSH concentration, while free T_3 (FT_3) and free T_4 (FT_4) concentrations remain within the normal reference ranges in a patient with no symptoms or with mild, nonspecific symptoms. Similarly, subclinical hyperthyroidism (associated with low serum TSH and normal FT_3 and FT_4 concentrations) is also a biochemical definition because hyperthyroid symptoms are often absent or nonspecific. Proposed mechanisms of drug-induced thyroid disorders are summarized in **Table 31-2**.[47-61] Drugs known to cause analytical interference with thyroid laboratory tests are not addressed in this chapter.

Table 31-1 Agents Implicated in Drug-Induced Thyroid Disorders[4-45]

Drug	Incidence	Level of Evidence[a]
HYPOTHYROIDISM		
Abiraterone[297]	NK	B
Adalimumab[212]	NK	C
Aldesleukin[4-9]	9%	B[b]
Alemtuzumab[210]	6.9%	A
Aloe[10]	NK	C

Amiodarone[11-13,249,251,252,254,298-302]	4.3–36%	A[c]
Axitinib[191-193,303-306]	6–92%	A
Bevacizumab[271]	23%	B[d]
Bexarotene[14-16]	6–40%	A
Cabozantinib[307,308]	15–78.8%	A
Carbamazepine[309,310]	NK	C
Cediranib[311,312]	13–56%	B
Dasatinib[190]	50%	B
Erlotinib[313]	NK	C
Escitalopram[221]	NK	C
Ethionamide[17-19,314]	NK	C
Imatinib[190]	13%	B
Infliximab[315,316]	NK	C
Interferon α[20-26,317-321]	2–84.6%	A[e]
Interferon β[27-34,322]	0.8–33%	B[e]
Iodinated compounds[35-39]	NK	A[f]
Ipilimumab[323,324]	1.5–1.6%	A
Kelp[40,41]	NK	B
Lenalidomide[269,325-330]	3.5–10%	B
Leuprolide acetate[42-44]	NK	C
Linifanib[331-333]	4.5–44%	A
Lithium[86,87,89,150,256,334-341]	1.5–35.4%	B
Motesanib[167,342,343]	5–41%	A
Nilotinib[190,344]	22%	B
Octreotide[345,346,347]	4%	B
Oxcarbazepine[310,348]	NK	C
Paroxetine[349]	NK	C
Pazopanib[194,350-353]	<10–62%	A
Pegylated interferon α[354-358]	6–12.8%	B[e]
Quetiapine[359-362]	NK	B[g]
Regorafenib[363]	31.4%	B
Rifampin[364-366]	NK	C

Sertraline[219]	NK	C
Sorafenib[138,140,174,303,305,370,379-382]	7–67.7%	A
Sunitinib[133,134,157,158,163,174-177,185,187,317,367-378]	3.4–85%	A
Thalidomide[383,384]	14%	B
Tivozanib[382,385]	22–30%	A
Vatalanib[386]	2%	B
Valproate[309,310,387]	NK	B
HYPERTHYROIDISM		
Adalimumab[388]	NK	C
Alemtuzumab[210,389,390]	14.8–33%	A
Amiodarone[11-13,249,251,252,254,299-302,391-394]	1.4–64%	A
Axitinib[191]	83%	C
Cabozantinib[308,395]	17.2%	C
Cyclosporin[396]	NK	C
Dasatinib[190]	20%	B
Epoprostenol[397]	6.7%	B
Everolimus[398]	NK	C
Nafarelin[399]	NK	C
Imatinib[190]	13%	B[h]
Infliximab[400,401]	NK	C
Interferon α[20-26,318,320,321,402]	5.8–15.3%	A[e]
Interferon β[27-34]	0.8–33%	B[c]
Iodinated compounds[35-39,104,403-405]	NK	A[f]
Ipilimumab[406]	NK	C
Lenalidomide[45,269,327,329]	2.35–2.7%	B
Leuprolide acetate[42-44]	NK	C
Leuprorelin[399]	NK	C
Lithium[86,87,89,150,293,334-339,407,408]	0.1–1.7%	B
Minocycline[214,215]	NK	C
Nilotinib[190,409]	33%	B
Pazopanib[194]	1%	B
Pegylated interferon α[354-358,410,411]	6–12.8%	B[e]

Pegylated interferon α-2a[412]	NK	C
Radioiodine[413-416]	2%	B[i]
Sibutramine[417]	NK	C[j]
Sorafenib[140,368,379]	3–5%	B
Sunitinib[134,163,368,418,419]	10–24%	B

NK = not known (case reports only).

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Thyroid dysfunctions have been reported in a randomized controlled trial evaluating aldesleukin in combination with antitumor vaccines.[8,420] Weill et al. reported thyroid abnormalities with aldesleukin in combination with lymphokine-activated killer cells.

[c] Connolly et al. reported thyroid abnormalities in an amiodarone plus β-blocker group; no thyroid abnormalities were reported with β-blocker monotherapy.[12]

[d] Study was conducted in pediatric patients who were receiving radiation therapy in combination with bevacizumab.[271]

[e] Thyroid abnormalities with interferon have been reported as monotherapy[21-34,354-358] or in combination with ribavirin.[20,411]

[f] This category comprises over 50 drug entities, including iodinated glycerol, potassium iodide, and povidone iodine (Table 33-3). Despite great variability in the quality of published reports for specific agents, the overall body of evidence suggests a consistent “class effect.” As such, iodinated compounds are classified here according to the highest level of evidence available for iodine rather than for individual agents.

[g] Although quetiapine does not meet the strict criteria for level B, a higher risk of hypothyroidism compared to placebo (OR 1.75, 95% CI 0.89–3.44) that required thyroid hormone replacement was observed in ~23% of patients suggests a higher level of causality.[362]

[h] One study conducted in 68 patients assessing the TSH levels before and after imatinib therapy found that imatinib does not impact thyroid function.[421]

[i] Jarvis et al. reported a prospective study conducted in a iodine-deficient region assessing the occurrence of iodine-induced thyrotoxicosis after iodinated contrast for CT and found that 2% of patients experienced subclinical hyperthyroidism.[416] Case reports identified a worsening in hyperthyroidism or autoimmune hyperthyroidism after administration of radioiodine.[413-415]

[j] Case report of a patient experiencing thyrotoxicosis and thyroiditis due to a sibutramine overdose.[417]

Drug-induced thyroid disorders have been reported mostly in adults. However, a number of thyroid abnormalities have been reported in association with drugs used in the treatment of children.[62-74]

Table 31-2 Proposed Mechanisms of Drug-Induced Thyroid Disorders[47-61,134,195,199,211-213,242,316,390,413,422-430]

Drug	Mechanism(s)
Acetylsalicylic acid (aspirin)	Decreased TSH release and/or response to TRH
Activated charcoal	Decreased TH bioavailability
Adalimumab[212]	Thyroid peroxidase antibody formation
Alemtuzumab[213,390]	Self-tolerance deficit in immune reconstitution occurring after lymphopenia, autoimmunity
Aluminum hydroxide	Decreased TH bioavailability
Amiodarone	Inhibit iodide binding/transport, inhibit iodination, inhibit endocytosis, inhibit proteolysis, inhibit intra-thyroidal deiodination of T_4, inhibit TH secretion, inhibit peripheral deiodination, inhibit TH receptor binding/uptake/action, increased TSH release and/or response to TRH, decreased thyrotropin receptor response, increased autoimmunity, dilatation of thyroid follicles with colloid, follicular cells having many residual bodies flattening
Amphetamines	Increased TSH release and/or response to TRH
Androgens (danazol)	Decreased TBG
Antipyrine	Inhibit iodination, inhibit coupling
Bexarotene	Inhibit TH receptor binding/uptake/action, decrease TSH secretion[199,211]
Bromine	Inhibit iodide binding/transport
Bromocriptine	Decreased TSH release and/or response to TRH
Calcium carbonate[51]	Decreased TH bioavailability
Carbamazepine	Increased hepatic metabolism
Chlorpromazine	Increased TSH release and/or response to TRH
Cholestyramine	Decreased TH bioavailability
Chromium	Decreased TH bioavailability
Cimetidine	Increased TSH release and/or response to TRH
Clofibrate	Increased TBG
Clomiphene	Increased TSH release and/or response to TRH
Clomipramine	Inhibit intra-thyroidal deiodination of T_4, inhibit peripheral deiodination
Colchicine	Inhibit endocytosis
Colestipol	Decreased TH bioavailability
Diazepam	Displacement from protein binding sites
Dietary/environmental goitrogens	Goitrogens
Dopamine/dopaminergics	Decreased TSH release and/or response to TRH
Estrogens (conjugated estrogen, ethinyl estradiol)	Increased TBG
Ethionamide[199]	Inhibit iodide binding/transport
Ferrous sulfate	Decreased TH bioavailability
Fluorine	Inhibit iodide binding/transport

Fluorouracil	Increased TBG
Free fatty acids (lipid emulsions in TPN)	Displacement from protein binding sites
Furosemide (>80 mg)	Displacement from protein binding sites, inhibit TH receptor binding/uptake/action
Glucocorticoids (dexamethasone)	Inhibit intra-thyroidal deiodination of T_4, decreased TBG, inhibit peripheral deiodination, decreased TSH release and/or response to TRH
Growth hormone (somatropin)	Decreased TSH release and/or response to TRH
Haloperidol	Increased TSH release and/or response to TRH
Heparins (fractionated and unfractionated)	Displacement from protein binding sites
Heroin	Increased TBG, decreased TSH release and/or response to TRH
Imatinib[195]	Increased hepatic metabolism
Infliximab[316]	Autoimmunity
Interferon α[54,211,242,425]	Destruction of thyroid cells, immune responses due to HLA overexpression, increased autoimmunity
Interferon γ[58]	Increased autoimmunity
Interleukin-1[58]	Inhibit iodination, inhibit TH secretion, modify the making of thyroglobulin and thyrocytes
Interleukin-2[199,211]	Induce inflammatory cytokines which can increase HLA-II and antigens on thyrocytes leading to autoimmune thyroiditis; increase thyroid antibodies and lymphocyte permeation in the thyroid, increase TSH secretion
Interleukin-6[199]	Decreased TSH secretion
Iodine-containing compounds (e.g., contrast agents)	Inhibit iodide binding/transport, inhibit iodination, inhibit endocytosis, inhibit proteolysis, inhibit intra-thyroidal deiodination of T_4, inhibit TH secretion, inhibit peripheral deiodination, increased TSH release and/or response to TRH, decreased thyrotropin receptor response
Isotretinoin[426]	Autoimmune thyroiditis
Ketoconozole	Inhibit coupling
L-asparaginase	Decreased TBG
Lenalidomide/thalidomide[211]	Decreased iodine uptake and thyroid hormone secretion interference, antiangiogenic activity
Levodopa/carbidopa	Decreased TSH release and/or response to TRH
Lithium	Inhibit iodide binding/transport, inhibit iodination, inhibit endocytosis, inhibit TH secretion, increased TSH release and/or response to TRH, increased autoimmunity, goitrogens
Metformin[61]	Decreased TSH release
Methadone	Increased TBG
Metoclopramide	Increased TSH release and/or response to TRH
Mifepristone[56,57]	Inhibit iodide binding/transport

Minerals (bromine, calcium, fluorine, nitrate, rubidium)	Goitrogens
Mitotane	Increased TBG
Nicotinic acid	Decreased TBG
NSAIDs (salicylates)	Displacement from protein binding sites, inhibit TH receptor binding/uptake/action
Octreotide	Decreased TSH release and/or response to TRH
Omeprazole[60]	Decreased TH bioavailability
Opiates (morphine)	Decreased TSH release and/or response to TRH
Orphenadrine	Displacement from protein binding sites
Pegylated interferon α[211]	Production of thyroid antibodies
Perchlorate[199]	Inhibit iodide binding/transport
Perphenazine	Increased TBG
Phenobarbital	Increased hepatic metabolism
Phentolamine	Decreased TSH release and/or response to TRH
Phenytoin	Displacement from protein binding sites, increased hepatic metabolism, inhibit TH receptor binding/uptake/action, decreased TSH release and/or response to TRH, phenytoin toxicity[a,430]
Pimozide	Decreased TSH release and/or response to TRH
Propranolol	Inhibit intra-thyroidal deiodination of T_4, inhibit peripheral deiodination
Propylthiouracil	Inhibit intra-thyroidal deiodination of T_4, inhibit peripheral deiodination
Radioiodine[413]	Increase thyroid antigens and radiation thyroiditis
Raloxifene[52]	Decreased TH bioavailability
Rifampin	Increased hepatic metabolism
Ritonavir[199]	Increase TSH secretion
Salicylamides (*p*-aminosalicylic acid, *p*-aminobenzoic acid)	Inhibit iodide binding/transport, inhibit iodination, inhibit coupling, displacement from protein binding sites, goitrogens
Serotonin antagonist (cyproheptadine, metergoline, methysergide)	Decreased TSH release and/or response to TRH
Sertraline	Increased hepatic metabolism
Sevelamer	Decreased TH bioavailability
Sodium polystyrene sulfonate	Decreased TH bioavailability
Spironolactone	Increased TSH release and/or response to TRH
St. John's Wort[199]	Increased TSH secretion
Sucralfate	Decreased TH bioavailability
Sulfonamides	Inhibit iodide binding/transport, inhibit iodination, inhibit coupling
Sulfonylureas (chlorpropamide,	Inhibit iodide binding/transport, inhibit iodination, inhibit coupling, displacement from protein binding sites

tolbutamide)[50]	
Sunitinib[134,427-429]	Iodine uptake inhibition, destructive thyroiditis, peroxidase inhibition, autoimmunity
Tamoxifen	Increased TBG
Thioamides (propylthiouracil, carbimazole, methimazole)	Inhibit coupling
Thioridazine	Decreased TSH release and/or response to TRH
Thyroid hormones (levothyroxine)	Decreased TSH release and/or response to TRH
Tumor necrosis factor α[58]	Inhibit iodination, inhibit TH secretion, modify the making of thyroglobulin and thyrocytes

NSAID = nonsteroidal anti-inflammatory drug, TBG = thyroid-binding globulin, TH = thyroid hormone, TRH = thyrotropin-releasing hormone, TSH = thyroid-stimulating hormone, TPN = total parenteral nutrition.

[a] Case report of a patient with phenytoin toxicity experiencing hypothyroidism while receiving thyroid replacement.

Patients infected with human immunodeficiency virus (HIV) and those with advanced acquired immunodeficiency syndrome are commonly affected with thyroid abnormalities.[75] Controversy exists regarding the association of highly active antiretroviral therapy (HAART) with the development of thyroid abnormalities in HIV-infected patients. Antiretroviral therapy has been associated with subclinical hypothyroidism, particularly after stavudine therapy.[75-77] In a cohort study of 350 HIV-infected patients, use of stavudine was associated with subclinical hypothyroidism in one subgroup of patients and with low serum FT_4 concentrations in another subgroup.[77] Graves disease also has been reported after immune restoration with HAART.[75] However, HIV-infected persons usually are clinically asymptomatic, and recommendations for routine thyroid screening remain controversial due to the absence of supporting evidence.[75]

EPIDEMIOLOGY

According to the 1999–2002 National Health and Nutrition Examination Survey (NHANES), the prevalence of hypothyroidism in the United States is 3.7% (overt 0.3%, mild 3.4%).[78] Females have a higher prevalence of hypothyroidism (4.2%) compared to males (3.1%). In contrast, only 0.5% (overt 0.2%, mild 0.3%) of the U.S. population has hyperthyroidism, with a higher incidence in females (0.8%) compared to males (0.1%). A 20-year follow-up study of 2,779 adults in Whickham, England, reported an annual incidence of overt hypothyroidism of 3.5 and 0.6 cases per 1,000 in women and men, respectively.[79] In women 75–80 years of age, the annual incidence increased to 14 cases per 1,000. With increased use of sensitive TSH assays, the diagnosis of subclinical thyroid disease has become more prevalent. In the United States, the prevalence of both hypothyroidism and hyperthyroidism appear to increase with age.[78] In the Whickham study, the annual incidence of hyperthyroidism was 0.8 cases per 1,000 women.[79] The prevalence of subclinical hyperthyroidism in the general population is 2–16%.[80] In women with underlying multinodular goiter, the prevalence of subclinical hyperthyroidism is 20%.[81]

The overall incidence of drug-induced thyroid disorders has not been clearly elucidated. The incidence of thyroid disorders associated with specific agents is listed in Table 31-1.[4-45]

Thyroid disorders associated with amiodarone and lithium are the most extensively documented. Amiodarone contains 37.3% iodine by weight; however, global variations in iodine intake influence the epidemiology of amiodarone-induced thyroid dysfunction.[82] In countries such as the United States and the United Kingdom where iodine intake is adequate, the incidence of amiodarone-induced hyperthyroidism and hypothyroidism is 1.7–3% and 13–22%, respectively.[80,83] In areas with inadequate iodine intake, however, hyperthyroidism occurs in 10–12% of amiodarone-treated patients, whereas only 6.4% have hypothyroidism.[80,83,84]

The epidemiology of lithium-induced thyroid dysfunction has also been well described, with hypothyroidism and goiter observed in 4–34% of patients exposed to the drug.[85-89] Exposure to lithium has also been implicated in the development of thyroid carcinoma, but the exact incidence remains unknown.[90-92] Published data concerning thyroid abnormalities associated with lithium therapy consist mostly of case reports, prevalence studies, retrospective studies, and small or short-term prospective studies. A 15-year evaluation of thyroid function in 150 patients using lithium reported a relative risk of clinical hypothyroidism of 8.4 in patients with antithyroid antibodies.[87]

Tyrosine kinase inhibitors have been associated with drug-induced hypothyroidism and hyperthyroidism at a rate of 38.5–68% and 20%, respectively.[93,94] Studies have reported improved survival in patients with metastatic renal cell carcinoma who developed hypothyroidism in association with tyrosine kinase inhibitor therapy.[94,95]

MECHANISMS

Specific mechanisms of drug-induced thyroid disorders include changes in autoregulation, inflammatory and autoimmune thyroiditis, and *de novo* development of increased levels of thyroid antibodies. Many mechanisms have not been fully elucidated, and some medications may have multiple thyroid-related effects. Most notable among the medications with relatively well-described mechanisms are iodides, amiodarone, lithium, interferon α, and tyrosine kinase inhibitors (e.g., sunitinib). Possible mechanisms by which drugs affect the thyroid gland are presented in Figure 31-1[96] and Table 31-2.[47-61]

DRUG-INDUCED HYPERTHYROIDISM

Iodine is a required substrate for thyroid hormone synthesis. Iodide enters the thyroid and becomes oxidized via thyroid peroxidase. The oxidized iodine atom is then added to selected tyrosyl residues within thyroglobulin. This process is referred to as organification. The optimal iodine intake is 150–250 mcg/day; consumption of 1,000 mcg or more per day is considered toxic.[97] In the presence of excess iodine, the thyroid normally inhibits organification, which is called the Wolff–Chaikoff effect.[37,98] This is a method of autoregulation that prevents excessive hormone production in response to an increase in the intrathyroidal iodine content. In individuals with a normal thyroid, the gland eventually escapes from this inhibitory effect and iodide organification resumes; nonetheless, the suppressive action of high intrathyroidal iodide content may persist in patients with underlying autoimmune thyroid disease. Patients residing in iodine-deficient areas often have multinodular goiter with loss of the Wolff–Chaikoff effect and autoregulation. Thus, iodine-induced hyperthyroidism, or Jod-Basedow phenomenon,occurs when patients, particularly those with multinodular goiters, increase their iodine intake or exposure.[38,99,100]

Medications with high iodine content include amiodarone, radiographic contrast media (e.g., diatrizoate), iodinated glycerol, and certain nonprescription preparations such as kelp tablets, Tri-iodine, and Iodoral.[101] A number of case reports have described iodine-induced hyperthyroidism from iodine-containing antiseptic solutions, contrast agents, and povidone-iodine soaked abdominal packs.[102,103] One report described the occurrence of subclinical hyperthyroidism in patients receiving iodinated radiographic contrast media for coronary angiography.[104] A list of iodine-containing medications is presented in **Table 31-3**.[38,105-107]

Each 200-mg amiodarone tablet contains 75 mg of iodine and releases approximately 6 mg of free iodine, exceeding the recommended daily intake, optimal daily allowance, and the toxic dosage range. In addition to its iodine content, the effects of amiodarone on the thyroid may be related to its structural homology with thyroid hormones. Thyroid dysfunction associated with amiodarone has been reported in pediatric and adult patients.[108-110] There are several proposed mechanisms for amiodarone-induced hyperthyroidism. Type 1 is related to the drug's high iodine content, and most often occurs in patients with pre-existing or underlying risk factors for thyroid disorders (e.g., autoimmune thyroid disease, multinodular goiter).[93,111-114] Type 2 results from a destructive inflammatory type of thyroiditis, causing excessive release of stored thyroid hormone into the systemic circulation.[113,114] This typically occurs in patients with ostensibly normal thyroid glands.[112,115-118] The inflammatory process is postulated to be caused by either the large iodine burden or, more likely, by a direct toxic effect of the drug.[119] Type 3 is known as a mixed form encompassing characteristics of both type 1 and type 2.[93,113,114] The time to onset of amiodarone-induced hyperthyroidism is quite variable and may range from 1 to 24 months after initiation of therapy.[120,121]

Interferon α has been associated with two types of drug-induced hyperthyroidism, a Graves-like immune disorder or an inflammatory destructive thyroiditis similar to that associated with amiodarone. Hashitoxicosis, an autoimmune thyroid disease in which patients present with hyperthyroidism followed by hypothyroidism, is more common than the Graves disease-like hyperthyroidism induced by interferon α.[122,123] Typically, the pattern of thyroid dysfunction with interferon α is biphasic, presenting as initial hyperthyroidism followed by hypothyroidism. A prospective observational study found that the average onset of drug-induced thyroid disease in hepatitis C patients taking interferon α was approximately 10 weeks.[124] In some cases, thyroid abnormalities may persist even after discontinuation of interferon α. In a prospective study of 201 patients with hepatitis C receiving interferon α, 11 patients developed biphasic thyroiditis.[125] All 11 patients achieved a sustained virologic response (SVR) or cure of their hepatitis C; however a meta-analysis did not find a positive correlation between the thyroiditis and SVR results. In addition, a case report described the development of thyroid peroxidase antibodies and biphasic thyroid disorder of hyperthyroidism and hypothyroidism following the use of pegylated interferon and ribavirin.[126]

Table 31-3 Iodine Content of Selected Medications and Dietary Supplements[38,105-107]

Medication	Route	Iodine Content (mcg)
Amiodarone	Oral	75,000/tablet
Calcium iodide	Oral	26,000/mL
Clioquinol (iodochlorhydroxyquin)	Topical	12 mg/g
Diatrizoate meglumine	Parenteral/urogenital	85,000–358,000/mL
Diatrizoate meglumine/sodium	Oral/parenteral	292,00–370,000/mL
Diatrizoate and iodipamide meglumine	Parenteral	380,000/mL
Diatrizoate sodium	Oral/parenteral/rectal/urogenital	600,000/g, 120,000–300,000/mL
Echothiophate iodide	Ophthalmic	5–41/drop
Ethiodized oil	Parenteral	370,000/mL
Hydriodic acid syrup	Oral	13,000–15,000/mL

Idoxuridine	Ophthalmic	358/mL
Iocetamic acid	Oral	465,000/mL
Iodamide meglumine	Parenteral	300,000/mL
Iodinated glycerol	Oral	15,000/tablet 6,000–25,000/mL
Iodine-containing vitamins (various)	Oral	54–200/tablet
Iodine		
Gel	Topical	9,000/g
Gel pad		9,000/g
Ointment		47,000/g
Solution		20,000/mL
Tincture		20,000–70,000/mL
Iodine and potassium iodide Lugol's solution, strong iodine tincture (various)	Topical	108,225–126,450/mL
Iodine and sodium iodide Iodine tincture (various)	Topical	40,321/mL
Iodipamide meglumine	Parenteral	257,000/mL
Iodixanol	Parenteral	270,000–320,000/mL
Iodized organic oils	Nasal	5,000–7,000/mL
Iodized salt	Oral	67/1.5 g (1 serving)
Iodoform gauze	Topical	4,800/100 mg
Iodoquinol	Oral	134,274–415,610/tablet
	Topical	6,000/g
Iohexol	Parenteral	140,000–350,000/mL
Iopamidol	Parenteral	250,000–370,000/mL
Iopromide	Parenteral	150,000–370,000/mL
Iothalamate meglumine	Parenteral/urogenital	81,000–282,000/mL
Iothalamate meglumine/sodium	Parenteral	400,000/mL
Iothalamate sodium	Parenteral	325,000–400,000/mL
Ioversol	Parenteral	160,000–350,000/mL
Ioxaglate meglumine/sodium	Parenteral	320,000/mL
Isopropamide iodide	Oral	1,321–1,800/tablet
Kelp (various)	Oral	100–4,200/g
Levothyroxine	Oral/parenteral	63/100 mcg
Liothyronine	Oral/parenteral	15/25 mcg
Liotrix	Oral	39/60–65 mg
Metrizamide (subarachnoid)	Parenteral	170,000–300,000/mL
Potassium iodide		
(Iosat, Thyro-Block)	Oral	99,385/tablet
(Pima)		49,692/mL
(SSKI)		764,500/mL
Potassium iodide and nicotinamide	Oral	115,000/tablet

hydroiodide		
Povidone-iodine 0.5–10% (various)	Topical	500–10,000/mL
Sodium iodide	Parenteral	85,000/mL
Thyroid, dessicated	Oral	29/65 mg
Tyropanoate sodium	Oral	430,000/capsule

Chronic lithium therapy has been associated with silent thyroiditis causing hyperthyroidism.[127,128] Silent thyroiditis, an inflammation of the thyroid gland, is often a self-limiting disorder characterized by transient thyrotoxicosis and subsequent hypothyroidism.[129] A retrospective review of 400 patients with thyroid disease reported a 4.7-fold increase in the likelihood of lithium exposure for patients with silent thyroiditis compared with Graves disease.[127] Lithium may also cause hyperthyroidism by acting as an immunomodulator. One study reported that 20% of patients receiving lithium therapy were found positive for thyroid microsomal and/or thyroglobulin antibodies that can lead to autoimmune thyroid disease.[130] In addition, one case report described thyroid storm from chronic lithium therapy.[131] The time to onset for lithium-induced hyperthyroidism is variable and not well defined.[127,128,131]

Recently, tyrosine kinase inhibitors, specifically sunitinib and sorafenib, have been shown to induce hyperthyroidism.[132] Some studies have reported initial hyperthyroidism before the onset of hypothyroidism.[133-137] One study reported development of sorafenib-induced hyperthyroidism in 23.9% of patients, which was characterized by suppressed TSH concentrations and increased free T_3/T_4 for a median duration of 2.3 months before ensuing hypothyroidism.[138] In a retrospective study, 4 of 15 patients developed sunitinib-induced hyperthyroidism. Three of these patients had elevated TSH concentrations before treatment, suggesting that patients with hypothyroidism may be at greater risk of sunitinib-induced hyperthyroidism.[139] Another study reported the onset of sorafenib-induced hyperthyroidism in 1 of 39 patients approximately 6 weeks after starting therapy.[140] A case report described a similar scenario of thyroid storm occurring 8 weeks after initiation of sorafenib therapy.[141] Following discontinuation of sorafenib, TSH concentrations increased but remained marginally suppressed. Additionally, a case report described a patient with sorafenib-induced thyrotoxicosis, which resolved with continued therapy and the addition of prednisone.[132] Symptoms of hyperthyroidism can also occur with excessive doses of thyroid hormone therapy (e.g., levothyroxine).[142]

DRUG-INDUCED HYPOTHYROIDISM

Excess iodine ingestion can also cause hypothyroidism. Iodide administration inhibits thyroid hormone synthesis and release and decreases iodide trapping.[143,144] Iodide-induced hypothyroidism ensues when the gland is unable to escape from the Wolff–Chaikoff effect. Iodine excess may also result in impaired TSH response, inhibition of proteolytic enzymes responsible for cleaving T_3 and T_4 from thyroglobulin before release, and inhibition of peripheral 5'-monodeiodinase conversion of T_4 to T_3.[2] Patients most susceptible to iodide-induced hypothyroidism include those with undiagnosed Hashimoto thyroiditis and those with a history of autoimmune thyroiditis not receiving thyroxine replacement. Consumption of an iodine-rich seaweed (kelp) diet has been associated with hypothyroidism and goiter in regions of Japan.[40,41,145,146] However, a short-term prospective clinical trial of euthyroid patients supplemented with kelp for 4 weeks found no clinical consequences of thyroid abnormalities despite evidence of chemical hypothyroidism.[147] With amiodarone, the Wolff–Chaikoff effect persists, resulting in a continuous decline in T_4 production. In addition, amiodarone may also inhibit thyroid hormone cellular uptake, pituitary and peripheral deiodination, and binding to thyroid receptor sites.[3] Amiodarone-induced hypothyroidism has been reported to occur during the first 3 to 18 months of therapy.[11,121]

Lithium impairs thyroid hormone synthesis by inhibiting iodide release from the thyroid tissue.[88,148-151] The resulting decrease in hormone production induces sustained TSH release, which can lead to development of a simple nontoxic goiter. The reported annual incidence of lithium-induced goiter is up to 50%.[152,153] However, regression of goiter was observed during a 15-year follow-up study in patients who continued to receive lithium treatment, and the proportion of palpable goiter decreased from 53% to 29%.[87] Lithium also may reduce iodine-concentrating capacity and inhibit synthesis of iodotyrosine and iodothyronines.[2] Lithium-induced hypothyroidism has been reported to occur within the first few months and up to 18 months of therapy.[154] One study reported the onset separated by sex.[150] Lithium-induced hypothyroidism occurred within the first 24 months of treatment in the female cohort and 59 months in the male cohort.[150]

Interferon α–induced hypothyroidism is more common than hyperthyroidism and typically follows episodes of hyperthyroidism. One study reported an association between the absence of SVR and the occurrence of central hypothyroidism in patients taking interferon α for hepatitis C.[155] The onset of hypothyroidism associated with interferon α has not been clearly elucidated, and, because symptoms of hypothyroidism are often attributed to the condition this drug is commonly used to treat (i.e., hepatitis C), the diagnosis of hypothyroidism in these patients may be delayed.[156]

The mechanism of tyrosine kinase inhibitor-induced hypothyroidism (specifically sunitinib) is postulated to involve impaired iodine uptake, partial inhibition of thyroid peroxidase, antiangiogenic effects (resulting in decreased blood flow and inhibition of vascular endothelial growth factor [VEGF] signals to the thyroid gland), destructive thyroiditis, capillary regression and/or constriction causing a decrease in vascularity, decrease in thyroid gland volume, thyroid hormone plasma membrane transport inhibition, and/or RET/PTC (rearranged in transformation/papillary thyroid carcinomas) kinase inhibition.[134,157-166] In addition, the mechanism by which motesanib causes hypothyroidism is thought to be due to changes in the metabolism or absorption of thyroxine.[167] Studies are underway to elucidate these mechanisms.[168] Additionally, a single-center Phase II study suggested that sorafenib may decrease the clearance of TSH, resulting in supranormal TSH concentrations.[169] The risk of hypothyroidism is positively correlated with the duration of treatment.[170] On average, the onset of symptoms was reported after 50 weeks of therapy.[134] Progressive worsening of pre-existing hypothyroidism is observed in most cases, but sudden development of severe hypothyroidism also has been described.[157] The literature hypothesizes that sunitinib causes more thyroid dysfunction compared to the other tyrosine kinase inhibitors due to its ability to target platelet-derived growth factor receptor (PDGFR) as well as vascular endothelial growth factor receptors 1 and 2 (VEGFR1 and VEGFR2).[171] Clinically significant thyroid dysfunction has also been reported with sorafenib, although not as frequently as with sunitinib.[140,172] However, a study of Japanese patients with metastatic renal cell carcinoma reported hypothyroidism in 46 (67.7%) patients treated with sorafenib.[138] In a 26-week Phase II study, levothyroxine requirements increased from 2.48 mcg/kg to 2.71 mcg/kg after sorafenib administration.[173] Another study reported 20.5% and 42.1% of patients taking sunitinib and sorafenib, respectively developed TSH concentrations higher than 3.77 µM/mL during the first month of therapy.[174] During the second month of treatment, 27.3% and 46.2% of patients receiving sunitinib and sorafenib, respectively, maintained elevated TSH concentrations. In a prospective study, thyroid replacement was required in 27% (16/59) of patients with sunitinib-induced hypothyroidism.[175] Eighty-five percent of patients taking sunitinib for metastatic renal cell carcinoma experienced hypothyroidism.[176] Additionally, of 80 patients receiving sunitinib in prospective clinical trials, 14 (18%) developed hypothyroidism.[177] The onset of sunitinib-induced hypothyroidism occurred within 10 weeks of therapy.[178] A retrospective study reported a high incidence of hypothyroidism in patients receiving axitinib (6 of 6 patients), sunitinib (9 of 15 patients), and sorafenib (6 of 12 patients).[139]

The occurrence of hypothyroidism in patients taking sunitinib and sorafenib for renal cell carcinoma may serve as a biomarker of efficacy, but the evidence is conflicting.[133,159,174,179-188] A retrospective study conducted in Brazil found an improvement in the overall response rate of patients with metastatic renal cell carcinoma who developed hypothyroidism during treatment compared to those who remained euthyroid (90% versus 20%, respectively, $p < 0.0001$).[188] In contrast, a meta-analysis conducted in more than 500 patients did not find an association between hypothyroidism and improved survival in tyrosine kinase inhibitor–treated patients with metastatic renal cell carcinoma.[189]

Second-generation tyrosine kinase inhibitors (i.e., imatinib, nilotinib, dasatinib) have also been reported to cause thyroid dysfunction in patients with Philadelphia chromosome-positive chronic myeloid leukemia.[190] Other observational studies suggest an association of axitinib with hypothyroidism; however, the sample sizes in these studies were relatively small.[191-193] Pazopanib has been reported to increase TSH concentrations above 5 milliunits/L in 29% of patients.[194] Imatinib and vandetanib have been associated with increased dosage requirements in thyroidectomized patients receiving thyroid hormone replacement therapy.[195,196,197]

Recently, a drug safety communication issued by the U.S. Food and Drug Administration (FDA) described the association of underactive thyroid in infants following exposure to iodinated contrast media.[198] This occurred in infants with serious medical conditions or that were premature. The FDA stated that this is a rare temporary occurrence and typically resolves without treatment or long-term effects.

ANTIBODY FORMATION

Thyroid autoantibodies, antithyroid peroxidase, and antithyroglobulin autoantibodies have been observed in patients with autoimmune thyroid diseases.[199] However, TSH receptor antibodies and thyroid-stimulating immunoglobulins that stimulate the TSH receptor are only seen in patients with hyperthyroidism. Antithyroid peroxidase antibodies are often present in patients experiencing hypothyroidism secondary to lithium or interferon α.[25,88] However, a 15-year follow-up study of 150 patients reported a 1.7% annual rate of new-onset autoimmunity associated with lithium therapy, a rate similar to that found in the general population.[79,87] Antithyroid peroxidase antibodies develop in 15% of patients receiving interferon α and have been reported in up to 53.3% of patients.[20,25,200-207] The link between interferon β-1b and antithyroid antibodies is less well defined. In a cohort of 156 patients using interferon β-1b, *de novo* antithyroid antibodies developed in six patients but persisted in only two patients.[31] Interpretation is confounded by the patients' underlying conditions (e.g., chronic hepatitis C, multiple sclerosis) that also have been associated with autoimmune complications and make it difficult to establish causality.[31,208,209]

Ninety-six percent of patients receiving alemtuzumab for the treatment of multiple sclerosis experienced thyroid dysfunction associated with thyroid autoantibodies.[210] Thyroid dysfunction has not been observed in patients taking alemtuzumab for cancer.[211] One case report found an increase in thyroid peroxidase antibodies after the administration of adalimumab for Crohn disease.[212] Compared to interferon β-1a, alemtuzumab was associated with a higher incidence of hyperthyroidism (0.9% versus 14.8%, respectively) and hypothyroidism (0.9% versus 6.9%, respectively).[210] The mechanism of alemtuzumab-induced thyroid autoimmunity is thought to be due to the self-tolerance deficit in immune reconstitution occurring after lymphopenia.[213]

It has been postulated that minocycline causes hyperthyroidism due to antibody formation or damage to thyroid follicular cells.[214,215] Thyroid peroxidase antibodies have also been associated with amiodarone-induced thyroid dysfunction.[216] One study found that antibody concentrations were higher in patients exposed to amiodarone for more than 24 months compared to shorter treatment exposures.[216]

OTHER MECHANISMS

The mechanism of HAART-induced hypothyroidism is not known. HIV infection has been associated with autoimmunity, and it is difficult to determine whether thyroid abnormalities found in HIV-infected patients are related to progression of the underlying disease or exposure to HAART.[75] Nevertheless, case reports suggest that protease inhibitors may accelerate glucuronidation of levothyroxine, thereby necessitating an increased dosage of thyroid hormone for replacement therapy.[217]

Sertraline may increase serum T_3 concentrations in the presence of normal TSH and T_4 concentrations.[218] One report noted that sertraline increased serum TSH concentrations in patients with hypothyroidism receiving levothyroxine therapy, although the mechanism was not established.[219] Additional case reports have described patients who experienced hypothyroidism with the combination of aripiprazole and sertraline as well as with escitalopram alone.[220,221]

The precise mechanism of central hypothyroidism induced by bexarotene is not clearly understood. Central hypothyroidism is a rare cause of hypothyroidism characterized by insufficient thyroid-hormone production resulting from impaired hypothalamic or pituitary function. Patients with central hypothyroidism often present with low FT_4 serum concentrations while TSH concentrations may be low, normal, or mildly elevated. A study that evaluated healthy individuals who received a single dose of bexarotene 400 mg/m^2 found that there was a rapid suppression of TSH without significant effects on serum prolactin, cortisol, glucose, insulin, triglyceride, or free fatty acids.[222] Bexarotene has been postulated to increase clearance of TSH independently of the effects of thyroid hormones.[222,223] Thyroid hormone replacement has been required in approximately 37% of the patients receiving bexarotene, with higher replacement needs in those receiving increased bexarotene doses.[16] Bexarotene-induced central hypothyroidism is often associated with a suppressed TSH and subsequent reduction in FT_4 serum concentrations. Clinical symptoms of hypothyroidism reverse within weeks of stopping therapy.[15,224]

Antitubercular medications have also been associated with hypothyroidism.[18,225-227] Ethionamide can inhibit thyroid-hormone synthesis, most likely because of its structural similarity to methimazole. This drug-induced hypothyroidism appears to be reversible with discontinuation of therapy.[18] Ethionamide use led to hypothyroidism in 6 of 207 patients, necessitating discontinuation of the medication.[227] A retrospective study of 186 patients in Lesotho with multidrug-resistant tuberculosis receiving combination therapy (ethionamide and para-aminosalicylic acid) reported hypothyroidism (TSH >10 milli-international units/L) occurring in 69% of the patients.[225] Similar results were reported with para-aminosalicylic acid and prothionamide (a thiocarbamide chemically related to ethionamide).[226] The mechanism by which these medications cause hypothyroidism is postulated to be due to the inhibition of iodine binding in the synthesis of thyroid hormone.[17,226,228,229]

Table 31-4 Signs and Symptoms Associated with Drug-Induced Thyroid Disorders[230,231]

Hypothyroidism

- Ataxia
- Bradycardia
- Coarseness or loss of hair
- Constipation
- Cool peripheral extremities
- Delayed tendon reflex relaxation
- Depression
- Dry skin and cold intolerance
- Dyspnea
- Fatigue and weakness
- Goiter
- Hoarse voice
- Hyperlipidemia
- Hypothermia
- Impaired hearing
- Irregular or heavy menses and infertility
- Memory and mental impairment

- Myalgias
- Paresthesias
- Puffy face, hands and feet (myxedema)
- Weight gain from fluid retention
- Yellow skin

Hyperthyroidism

- Alteration in appetite
- Atrial fibrillation
- Changes in vision, photophobia, eye irritation, diplopia
- Decreased menstrual flow
- Exertional intolerance and dyspnea
- Exophthalmos
- Fatigue and muscle weakness
- Frequent bowel movement or diarrhea
- Heat intolerance and sweating
- Impaired fertility
- Lid retraction or lag
- Mental disturbances
- Nervousness and irritability
- Palpitations
- Peripheral edema
- Pretibial myxedema
- Sleep disturbances (including insomnia)
- Sudden paralysis
- Tachycardia
- Thyroid enlargement
- Tremor
- Weight loss or gain

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The clinical features associated with drug-induced hyperthyroidism and drug-induced hypothyroidism are often related to accelerated or impaired metabolism, respectively, or to an underlying autoimmune process. Specific signs and symptoms are presented in **Table 31-4**.[199,230,231] The severity, duration, and extent of illness may vary greatly from patient to patient.

Unfortunately, the association between drug dose and duration and dose response and the development of hypo- or hyperthyroidism is not well established for many of the agents implicated in these drug-induced diseases. Possible risk factors that should be evaluated include the patient's age, sex, thyroid hormone status, iodine status, overall nutritional status, and other coexisting medical conditions (e.g., previous thyroid disease, diabetes, rheumatoid arthritis, pernicious anemia). In countries where the population receives adequate iodine supplementation, such as the United States, it is generally reasonable to assume that iodine deficiency is not a factor.

In patients presenting with symptoms of hyperthyroidism, primary causes of the disease should be excluded. These include Graves disease, toxic multinodular goiter, subacute thyroiditis, toxic adenoma, and thyrotoxicosis factitia. Common causes that should be considered in the differential diagnosis of hyperthyroidism are included in **Table 31-5**. Some patients may present with new-onset or worsening heart failure, atrial fibrillation, or angina. In elderly patients with unexplained weight loss, an evaluation for possible malignancies is indicated.

Individuals with symptoms of hypothyroidism should be evaluated for primary causes such as Hashimoto thyroiditis, dyshormonogenesis, iodine deficiency, infiltrative diseases (e.g., amyloidosis, sarcoidosis), and transient subacute thyroiditis. Central hypothyroidism associated with secondary (i.e., hypopituitarism) and tertiary (i.e., hypothalamic disease) causes also should be excluded. Early symptoms such as constipation, fatigue, weight gain, and dry skin may be incorrectly attributed to aging. Common causes that should be considered in the differential diagnosis of hypothyroidism are included in Table 31-5.

Table 31-5 Conditions to Consider in the Differential Diagnosis of Drug-Induced Thyroid Disorders

Hypothyroidism

- Autoimmune thyroiditis (e.g., Hashimoto disease)
- Congenital cretinism (maternal induced)
- Dyshormonogenesis (e.g., defect in hormone synthesis/ transport/action)
- Deficiency of TSH (e.g., pituitary or hypothalamic dysfunction)
- Goitrogens (e.g., cabbage/rutabagas/turnips)
- Iatrogenic thyroid gland destruction (e.g., surgery/radiation)
- Idiopathic atrophy
- Iodine deficiency

Hyperthyroidism

- Choriocarcinoma[231]
- Functional thyroid cancer metastases[231]
- Graves disease[231]
- Pituitary resistance to thyroid hormone
- Thyroiditis[231]
- Thyrotoxicosis factitia (self-administered thyroid hormone)[231]
- Toxic multinodular goiter
- Toxic uninodular goiter (Plummer disease)
- TSH-producing adenoma[231]
- Tumors (e.g., thyroid/pituitary/trophoblastic tumors/struma ovarii)[231]

TSH = thyroid-stimulating hormone.

Laboratory evaluation of thyroid function is also required for patients with suspected drug-induced thyroid disease. A serum TSH concentration is the single most important diagnostic test.[199,231] A suppressed or undetectable serum TSH concentration along with elevated thyroid hormones is indicative of hyperthyroidism, whereas a suppressed or undetectable serum TSH concentration with a normal T_3 and FT_4 suggest subclinical hyperthyroidism.[231] Conversely, an elevated serum TSH and a low serum FT_4 concentration indicate hypothyroidism, while an elevated serum TSH and a normal serum FT_4 concentration without symptoms signifies subclinical hypothyroidism.[199] Thyroid diagnostic tests should be interpreted with caution in patients with unstable thyroid function or in the presence of hypothalamic-pituitary-thyroid axis abnormalities.[199] Before a diagnosis of drug-induced thyroid disease can be confirmed, nonthyroidal systemic illnesses and other causes associated with alterations in thyroid function tests must be excluded. A number of conditions can result in altered thyroid hormone metabolism and may even be present in patients who appear clinically euthyroid. The euthyroid sick syndrome is characterized by alterations in thyroid laboratory parameters without clinical disease. Such conditions may include malnutrition, fasting, infectious diseases, malignancy, surgery, chronic diseases (cardiac, pulmonary, renal, hepatic), acute psychiatric illness, and metabolic disorders (e.g., diabetes). Interpretation of laboratory findings in such settings may be difficult, and treatment should be directed at correction of the underlying illness.

In circumstances in which serum TSH and FT_4 results are equivocal for the definitive diagnosis of hyperthyroidism, evaluation of serum total T_3 and FT_3 concentrations may be helpful. Medications that modify TSH secretion, alter thyroid-binding globulin (TBG), displace thyroid hormone from protein-binding sites, increase hepatic metabolism, decrease T_4-to-T_3 conversion, or impair T_4 absorption (Table 31-2) may confound interpretation of laboratory findings. In addition to medications, certain disease states can alter serum TBG concentrations. For example, patients with nephrotic syndrome may present with low total serum T_4 concentrations due to lowered serum TBG concentrations, but serum FT_4 and TSH concentrations often remain normal.[232]

Subclinical disease should always be considered in the differential diagnosis of drug-induced thyroid dysfunction. Management of subclinical hypothyroidism is controversial because the risks and benefits of treatment are not well understood.[199] Nonetheless, progression to overt hypothyroidism, can lead to significant health risks, such as hyperlipidemia and associated atherosclerotic complications.[233] Patients with subclinical hyperthyroidism, especially the elderly, may be at increased risk of cardiovascular complications (e.g., atrial fibrillation) and osteoporosis.[199]

It can be difficult to differentiate between the types of amiodarone-induced hyperthyroidism. In general, serum TSH concentrations are suppressed and serum FT_4 concentrations are elevated. In type 1 amiodarone-induced thyrotoxicosis, increased thyroidal blood flow and hypervascularity are present on color-flow Doppler sonography. In contrast, type 2 amiodarone-induced thyrotoxicosis is characterized by decreased or normal thyroidal blood flow on sonography.[234] A combination of type 1 and type 2 amiodarone-induced thyrotoxicosis can also occur, thereby making the diagnosis challenging. Elevations in serum interleukin-6 concentrations also have been reported in type 2 disease, but changes are negligible in type 1.[235] The time to onset of amiodarone-induced hyperthyroidism is quite variable and may range from 1 to 24 months after initiation of therapy.[120,121]

Lithium-induced thyroid changes may occur within a few weeks of therapy initiation but are most often observed after prolonged treatment.[87,88,150] However, one study found no correlation between thyroid dysfunction and duration of treatment (i.e., thyroid function was similar in patients taking lithium for 10–20 years and for more than 20 years).[236]

RISK FACTORS

Risk factors for drug-induced thyroid dysfunction are listed in **Table 31-6**.[237] A personal or family history of thyroid disease or presence of thyroid antibodies is associated with an increased risk of drug-induced thyroid illness. Without normal thyroid adaptive mechanisms, excess iodine intake may result in hyperthyroidism, hypothyroidism, or goiter. The clinical presentation of drug-induced thyroid dysfunction is generally more severe in patients who already have an underlying thyroid condition. Autoimmune thyroiditis, such as Hashimoto disease, has been implicated as a risk factor.[238] Women are considered to be at greater risk for thyroid disease and drug-induced thyroid dysfunction. Partial thyroidectomy, pre-existing or new thyroid autoimmunity, a history of radioactive iodine administration, postpartum thyroid disease, and previous thyroid damage have been identified as risk factors for the development of drug-induced thyroid disease.

Table 31-6 Risk Factors for Drug-Induced Thyroid Disorders[237]

- **Current Thyroid Abnormality**
  - Hashimoto thyroiditis
  - Thyroid autoimmunity
  - Partial thyroidectomy
- **Previous Thyroid Abnormality**
  - Previous thyroid disease

    - History of radioactive iodine administration
    - History of postpartum thyroid disease
- **Family History of Thyroid Disease**
- **Female Sex**

Studies assessing risk factors for interferon α–induced thyroid dysfunction confirmed that female sex, white race, nonsmokers, presence of thyroid peroxidase antibodies before treatment, and patients with a history of thyroid disease are at the greater risk.[239-245] Also, patients taking interferon α for hepatitis C are more likely to develop thyroid dysfunction compared to those with hepatitis B.[246,247]

Patients <62 years old may also be at increased risk of developing amiodarone-induced thyrotoxicosis.[248-252] Additionally, patients with congenital heart disease taking amiodarone were more likely to experience amiodarone-induced thyrotoxicosis if their body mass index (BMI) was <21 or if a goiter was present.[253] Female sex and the presence of antithyroid peroxidase antibodies also have been associated with an increased risk of amiodarone-induced hypothyroidism.[254,255]

Additional studies in lithium-treated patients found that female sex, use of antidepressants and valproate sodium, younger age (<60 years), as well as elevated lithium serum concentrations may increase the risk of hypothyroidism.[256,257]

Nutritional deficiencies, malnutrition, and dietary goitrogens are other potential risk factors for the development of thyroid abnormalities. Foods that may be goitrogenic include chou moellier, cassava, sorghum, corn, millet, cabbage, kale, Brussel sprouts, cauliflower, kohlrabi, turnip, rutabaga, mustard, and horseradish.

Iodine deficiency is the leading cause of goiter. National iodine supplementation programs are designed to protect populations against chronic iodine deficiency. Most industrialized countries provide dietary iodine supplements, and the World Health Organization has been active in promoting universal supplementation programs. Because of the possible effects of selenoenzymes on control of thyroid hormone metabolism, a diet low in selenium may be associated with increased serum T_3, resulting in subclinical hyperthyroidism.[258] In addition to thyroid disease associated with nutritional deficiencies, endemic goiter may result from consumption of foods rich in antithyroid substances such as cyanogenic glucosides, thioglucosides, thiocyanate, or goitrin. Goiter has occurred as a result of excessive direct or indirect (typically transferred through cow's milk) exposure to these compounds.

MORBIDITY AND MORTALITY

Drug-induced thyroid disease may result in clinical manifestations of hypothyroidism, hyperthyroidism, or goiter. Left untreated, overt hyperthyroidism may result in serious medical complications, including structural thyroid gland changes, osteoporosis, exaggerated hyperthyroidism symptoms, and cardiac complications such as dysrhythmias and heart failure, which may be associated with substantial morbidity and mortality. Severe, uncontrolled hypothyroidism can result in a decompensated thyroid state leading to hypothermia, biochemical abnormalities, respiratory failure, cardiovascular collapse, and myxedema coma, which can be fatal. A goiter, when substantially enlarged, may be cosmetically unacceptable and lead to respiratory distress and swallowing difficulties that, in some cases, can be relieved only by surgical intervention.

PREVENTION

Baseline laboratory tests and physical examination, including examination of the thyroid gland, should be performed in all patients receiving a drug with the potential to cause thyroid dysfunction (Table 31-1).[4-45] Except in patients who have an abnormal hypothalamic-pituitary-adrenal axis (e.g., those with Cushing syndrome or Addison disease), a baseline serum TSH concentration (and possibly a serum FT_4 determination) should suffice. In patients with pre-existing thyroid dysfunction, a risk-benefit assessment should be performed to determine the appropriateness of initiating therapy with any drug known to cause thyroid disease. During therapy, laboratory evaluation should be performed periodically, with the frequency based on the patient's risk factors for thyroid disease and the likely seriousness of drug-induced thyroid disease should it occur.

Patients receiving bexarotene therapy may benefit from monitoring of FT_4 for management of central hypothyroidism because serum TSH alone cannot reliably be used as an indicator of thyroid status.[15] A cohort study of patients with multiple sclerosis taking interferon β, reported an increased incidence of thyroid dysfunction and thyroid autoimmunity within the first year of treatment; therefore, monitoring during the first year is advised.[259] In addition, thyroid function should be assessed for at least 6 months after the discontinuation of interferon-based therapy.[260]

In patients receiving therapy with amiodarone, interferon α, or lithium, laboratory tests (e.g., TSH, FT_4, thyroid antibodies) should be done at baseline and at 3- to 6-month intervals, and if symptoms occur or dosages are modified.[58,156,231,261] A case series reported six patients who experienced thyrotoxicosis more than 60 days after discontinuation of amiodarone, four of which received amiodarone for short-term therapy.[262] Additionally, one report noted amiodarone-induced thyrotoxicosis 6 months after treatment discontinuation.[263] These studies suggest the need for long-term monitoring of thyroid function tests even after withdrawal of therapy.[264] When amiodarone-induced hyperthyroidism occurs, the American Thyroid Association and the American Association of Clinical Endocrinologists recommend conducting follow-up tests to determine if type 1 (iodine-induced) or type 2 (thyroiditis) hyperthyroidism is present.[231] A retrospective study also suggested the use of radioiodine (800 MBq [22 mCi]) as a preventative therapy for euthyroid patients who were hyperthyroid prior to starting amiodarone.[265,266] Although serum interleukin-6 concentrations may be elevated with destructive thyroid disease (e.g., type 2 amiodarone-induced hyperthyroidism), this test is not readily available or consistently helpful.

Patients receiving alemtuzumab therapy should have laboratory assessments at baseline, every 2–3 months, or if the patient is symptomatic.[213] To detect hypothyroidism earlier, thyroid function should be monitored at the beginning of each sunitinib treatment cycle.[162,183] Regular thyroid function monitoring in patients taking lenalidomide is recommended monthly or every 2 months.[267-269] In addition, patients taking carbamazepine should have thyroid function assessed monthly for the first 4 months and every 6–12 months thereafter.[270] Thyroid hormone concentrations should be monitored every 6–8 weeks in patients taking bevacizumab.[271]

A conservative approach to minimize the risk of potential complications is to use the lowest effective dose of drugs that may cause thyroid disorders for the shortest time possible. Because the onset of drug-induced thyroid disease is highly variable, routine laboratory monitoring, patient education, and vigilance for symptom onset are important components of disease surveillance. Specific strategies for prevention are summarized in **Table 31-7**.

Table 31-7 Approaches to Help Prevent Drug-Induced Thyroid Disorders

- Avoid drugs known to cause thyroid disorders
- Avoid goitrogens
- Consume a sufficient amount of iodine to prevent a low iodine state
- Consume an adequate amount of selenium
- Correct underlying thyroid abnormalities
- Educate patients and families on the possible symptoms associated with drug-induced thyroid disease and need to promptly inform their healthcare providers of symptom occurrence
- Screen for thyroid abnormalities before initiating therapy and periodically thereafter
- Use alternative therapies that are not associated with thyroid disease in high-risk patients when possible

MANAGEMENT

In a patient with new-onset thyroid dysfunction, drugs with the potential to cause thyroid irregularities should be discontinued, if feasible. Resolution of the thyroid abnormality may require several months and, in some cases, the condition may be irreversible. Rechallenge with the offending agent should not be attempted unless medically necessary. If the drug cannot be discontinued or if the condition does not resolve after discontinuation, appropriate antithyroid therapy or thyroid hormone replacement may be required (**Table 31-8**).

Table 31-8 Management of Drug-Induced Thyroid Disorders

Hypothyroidism

- Thyroid replacement (e.g., levothyroxine)

Hyperthyroidism

- Adrenergic β-receptor blockers
- Calcium-channel blockers
- Glucocorticoids
- Iodides
- Iodinated contrast media
- Thioamides (e.g., methimazole, propylthiouracil)
- Thyroidectomy

Drug-induced hypothyroidism is best treated with levothyroxine. The initial dose should be 1.6–1.7 mcg/kg/day, and the dose should be titrated upward, as necessary, every 4–6 weeks until the patient is clinically and chemically euthyroid. Lower initial doses (e.g., 25 mcg) and a more gradual dosage escalation (12.5–25 mcg every 6–8 weeks) may be necessary in the elderly and in those with clinically significant cardiovascular disease (e.g., angina, palpitations). Serum TSH and FT_4 concentrations should be determined after levothyroxine has reached a steady state (approximately 6–8 weeks after the initiation of therapy).

For patients with amiodarone-induced hypothyroidism, levothyroxine requirements may be higher than usual due to inhibition of pituitary and peripheral conversion of T_4 to T_3.[118] Managing amiodarone-induced hyperthyroidism is more complex because it is often difficult to distinguish between the two types of thyrotoxicosis. Antithyroid medications, such as methimazole or propylthiouracil, combined with potassium perchlorate often are used for the treatment of type 1 amiodarone-induced hyperthyroidism as its underlying pathogenesis is related to the drug’s high iodine content, which results in excessive thyroid-hormone synthesis.[231,272,231,273] In contrast, type 2 amiodarone-induced hyperthyroidism is often unresponsive to the thioamides, and treatment with corticosteroids is most effective because of the underlying inflammatory process.[117,272,231,273,274] The dose of prednisone (or equivalent doses of other corticosteroids) can range from 30 mg daily for 2 weeks followed by gradual tapering and discontinuation after 3 months of therapy to doses of 0.5 mg/kg/day until euthyroidism is restored.[117,275] Baseline FT_4 and thyroid volume (measured by ultrasonography) appear to be independently useful in identifying patients at risk for delayed treatment response with corticosteroids.[275] Because of the potential for additive cardiac effects with amiodarone, adrenergic β-receptor blockers or calcium-channel blockers are typically not recommended for control of hyperthyroid symptoms.

Results from studies of patients with amiodarone-induced hyperthyroidism suggest that there is no difference in the duration of thyrotoxicosis between patients who continue or temporarily discontinued amiodarone therapy.[274,276-278] This suggests that amiodarone may be continued in cases in which withdrawal could result in detrimental cardiac consequences, and the use of alternative antiarrhythmic agents is contraindicated.[276] Discontinuation of amiodarone does not result in complete resolution of thyroid abnormalities, and cases of amiodarone-induced hyperthyroidism have been reported several months after cessation of therapy.[279,280] In patients who require continued amiodarone therapy or who are nonresponsive to medical therapy, thyroidectomy can be considered for cosmetic or medical reasons, particularly dysphagia, respiratory difficulty, or voice alterations.[112,114,231,281-285] A case report also described the use of therapeutic apheresis prior to thyroidectomy to reduce thyroid hormone concentrations.[286]

Radioactive iodine is typically not recommended because the gland is already iodine-loaded, thereby interfering with uptake and retention of radioactive iodine. In a recent study, the efficacy of radioiodine (RAI, 131-I) therapy for the management of type 2 amiodarone-induced thyrotoxicosis was compared between patients with a high or normal radioiodine uptake who received amiodarone in the past and patients with low radioiodine uptake currently taking amiodarone.[287] This study found 131-I (22 mCi) to be an effective alternative option for patients unable to undergo thyroidectomy. However, death occurred in 10% of patients who had received amiodarone in the past compared to 44% in those with low radioiodine uptake who were currently receiving the drug. Several other studies that evaluated the use of radioiodine therapy for amiodarone-induced thyrotoxicosis in patients with low radioiodine uptake reported clinical benefit without any reported deaths.[288,289] A case report described a patient with Eisenmenger syndrome who developed amiodarone-induced thyrotoxicosis and was successfully treated with 131-I (22 mCi) despite continuation of amiodarone therapy.[290] In a second report involving another patient with Eisenmenger syndrome, total thyroidectomy resulted in rapid resolution of thyrotoxicosis and an uncomplicated recovery, so that surgery was suggested as a treatment option for amiodarone-induced thyrotoxicosis.[291] Conversely, a retrospective analysis of amiodarone-induced thyrotoxicosis in patients with congenital heart disease found that thyrotoxicosis, particularly in asymptomatic individuals, often can be managed without the need for surgical or medical intervention.[277]

β-blockers can be administered if needed for symptomatic relief in patients with interferon β–induced hyperthyroidism, although the disorder typically resolves spontaneously within weeks to several months after drug discontinuation. Clinical practice guidelines recommend attempting to identify the etiology of the interferon α or interleukin-2-induced hyperthyroidism (e.g., thyroiditis versus Graves disease) and to treat the patient accordingly.[231] Interferon α–induced hypothyroidism is usually transient, resolving spontaneously within weeks to several months after drug discontinuation.[124] In patients with interferon α–induced hypothyroidism who are asymptomatic, T_4 therapy is often not necessary. If levothyroxine treatment is initiated, it should be discontinued 6 months after the cessation of interferon α therapy and thyroid status reevaluated to determine the need for continued replacement. Case reports have described the use of radioactive iodine as a treatment option for patients with interferon α–induced hyperthyroidism with mild Graves ophthalmopathy in which β-blockers and antithyroid medications are ineffective.[242,292]

Iodine-induced hyperthyroidism should be treated with β-blockers either as monotherapy or as combination therapy with methimazole.[231]

During the occurrence of lithium-induced thyrotoxicosis, discontinuation of lithium is not recommended due to the potential for further exacerbation of thyrotoxicosis.[293,294] However, several case reports have described patients experiencing resolution of thyrotoxicosis following lithium withdrawal.[293,295]

INFORMATION FOR PATIENTS

Individuals with a history of thyroid disease appear to be at increased risk for developing drug-induced thyroid complications. Patients who receive medications known to be associated with thyroid abnormalities should be taught to recognize and instructed to report symptoms of hypothyroidism, hyperthyroidism, or gland enlargement. Specifically, they should be advised to consult their primary healthcare providers if they experience fatigue, constipation, palpitations, nervousness, heat or cold intolerance, or any other new or unusual symptoms (Table 31-4).[199,230] Certain weight-loss preparations may contain thyroid hormones or excessive amounts of iodine.[296] Given that these preparations as well as some herbal and other alternative therapies have the potential to induce thyroid dysfunction or interfere with thyroid-related medications, their use without medical supervision should be discouraged.

Note: The authors wish to acknowledge the work of Dr. Nayahmka McGriff-Lee, who authored this chapter in a previous edition.

CHAPTER 32

Hypothalamic, Pituitary, and Adrenal Diseases

Andrew Y. Hwang, Steven M. Smith, and John G. Gums

Drug-induced disorders of the hypothalamus, pituitary, and adrenal glands are difficult to classify because of the complex interrelationship of the various endocrine glands. Nonetheless, the most commonly reported are those caused by adrenocortical dysfunction and excess prolactin secretion by the anterior pituitary. Adrenal glands are responsible for the secretion of catecholamines and three hormones responsible for the regulation of some of the most vital processes in the body. Aldosterone, the main end product of mineralocorticoid production, is secreted preferentially by the zona glomerulosa and is responsible for electrolyte and volume homeostasis. The zona fasciculata is primarily responsible for glucocorticoid production, mainly cortisol, and controls fat, protein, and glucose metabolism. The zona reticularis is primarily responsible for production of the sex steroids (estrogen and testosterone) that control the development of primary and secondary sex characteristics.

The pituitary gland, also known as the hypophysis, is under the control of the hypothalamus through direct nerve stimulation (posterior lobe) and by the actions of inhibitory and stimulating hormones (anterior lobe) such as thyrotropin-releasing hormone and corticotropin-releasing hormone (CRH). The anterior lobe of the pituitary gland is responsible for the synthesis of growth hormone (GH), prolactin, luteinizing hormone, follicle-stimulating hormone, thyroid-stimulating hormone, and adrenocorticotropic hormone (ACTH). In addition, vasopressin, also known as antidiuretic hormone, and oxytocin are synthesized in neurons of the hypothalamus, stored in the posterior lobe of the pituitary, and released upon direct nerve stimulation. The complex interplay between the hypothalamus, pituitary, and adrenal glands is commonly referred to as the hypothalamic–pituitary–adrenal (HPA) axis (**Figure 32-1**).

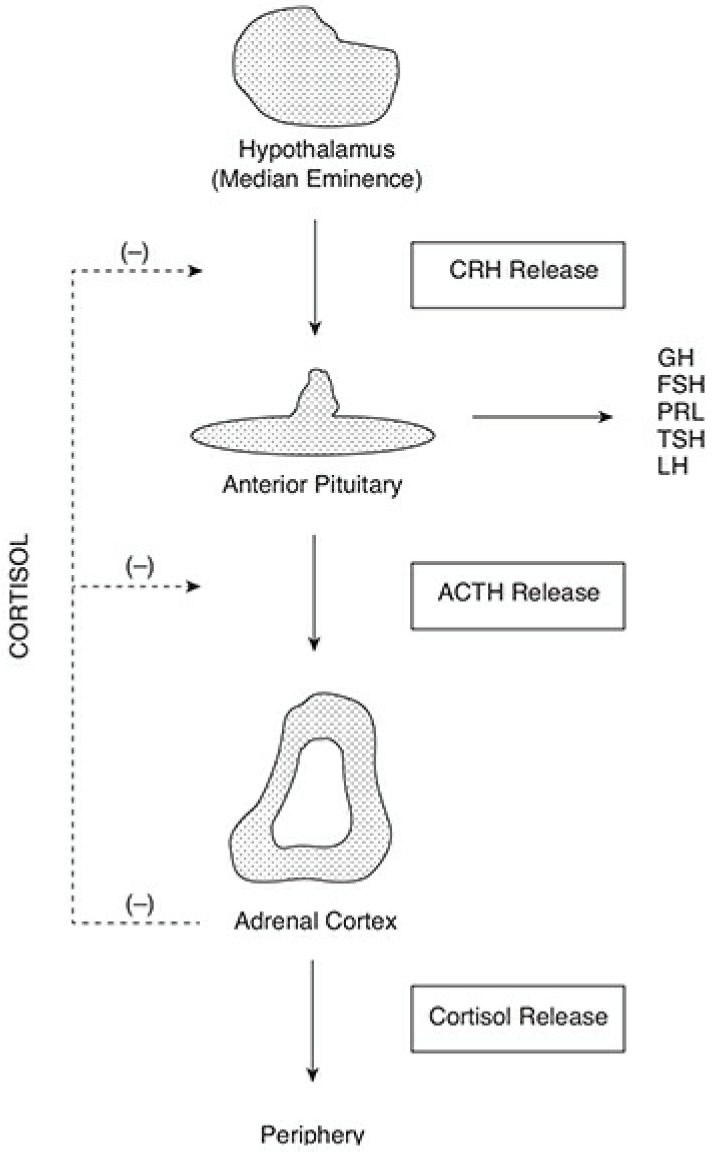

FIGURE 32-1 Hypothalamus

ACTH = adrenocorticotropin, CRH = corticotropin-releasing hormone, GH = growth hormone, FSH = follicle-stimulating hormone, LH = luteinizing hormone, PRL = prolactin, TSH = thyroid-stimulating hormone.

GLUCOCORTICOID EXCESS (CUSHING SYNDROME)

In 1932, Cushing first described a syndrome of pituitary basophilism that attracted national attention. Until that time, no definitive diagnosis was available for patients with unexplained central obesity, striae, osteoporosis, weakness, hypertension, and diabetes mellitus. Daughaday discovered elevated steroids in the urine of patients with this clinical presentation, and the syndrome was at last correctly explained as an excess of cortisol in the plasma (hypercortisolism).

CAUSATIVE AGENTS

Specific drugs that have been reported to induce Cushing syndrome are listed in **Table 32-1**.[1-40] Prolonged or excessive administration of corticosteroids is the most common cause of drug-induced Cushing syndrome; these drug-induced cases can occur following administration of virtually any corticosteroid by any route.[1-24,41-43] Other drug-induced causes include progestins and ACTH administration.

EPIDEMIOLOGY

The incidence of drug-induced Cushing syndrome in the general population is unknown, although it likely substantially exceeds the estimated 1 to 3 cases per million person-years observed in persons with Cushing syndrome secondary to pituitary tumors or adrenal adenomas and carcinomas (collectively referred to as endogenous Cushing syndrome).[44,45] Approximately 2–5% of obese patients with uncontrolled type 2 diabetes and hypertension screen positive for Cushing syndrome, although scarce data exist to help differentiate the drug-induced disease from other causes. Nevertheless, the vast majority of Cushing syndrome cases are thought to be drug-induced, and the syndrome has been recognized with increased frequency as the use of glucocorticoids for a wide range of nonendocrine diseases has expanded.

MECHANISMS

Mechanisms for drug-induced Cushing syndrome are listed in **Table 32-2**. In vivo, glucocorticoid drugs resemble the naturally occurring glucocorticoid, cortisol, and bind with high affinity to specific cytoplasmic glucocorticoid receptors (GRs) found in virtually all tissues of the body. This binding induces a response by modifying transcription and ultimately by causing changes in protein synthesis that can produce adverse physiologic effects similar to those seen in classic Cushing syndrome (hypercortisolism secondary to a pituitary tumor). Increased sensitivity to glucocorticoids may play a role in some cases of drug-induced Cushing syndrome, especially when the route of administration is expected to result in minimal systemic exposure.[46] However, drug–drug interactions causing inhibition of the metabolism of glucocorticoids—particularly those with high first-pass metabolism such as fluticasone, budesonide, and mometasone—also may precipitate Cushing syndrome.[5-11] Medroxyprogesterone acetate (MPA) and megestrol acetate possess glucocorticoid-like activity and appear to induce Cushing syndrome through their ability to bind to GRs.[26-31,41,42] ACTH or drugs that stimulate ACTH release from the pituitary (e.g., γ-hydroxybutyric acid) may also contribute through the direct stimulation of the adrenal glands to release endogenous glucocorticoids.[25,41]

Table 32-1 Agents Implicated in Drug-Induced Cushing Syndrome

Drug	Incidence[a]	Level of Evidence[b]
ORAL GLUCOCORTICOIDS		
Budesonide[38]	NK	C
Prednisolone[1]	5%	A
INHALED GLUCOCORTICOIDS		
Beclomethasone dipropionate[3,4]	NK	B
Budesonide[3,9]	NK	B
Fluticasone propionate[2-7,10,11,39]	NK	B
Mometasone furoate[7]	NK	B
Triamcinolone acetonide[3]	NK	B
NASAL GLUCOCORTICOIDS		
Fluticasone propionate[5,8]	NK	C
Fluticasone furoate[11]	NK	C
TOPICAL GLUCOCORTICOIDS		
Betamethasone[18]	NK	C
Clobetasol propionate[13,14,16]	NK	C
Dexamethasone[15]	NK	C
Hydrocortisone butyrate[17]	NK	C
Prednisolone acetate[23,24]	NK	C

Triamcinolone acetonide[12]	NK	C
INJECTABLE GLUCOCORTICOIDS		
Triamcinolone acetonide[19-22,40]	NK	C
PROGESTINS		
Medroxyprogesterone acetate[26-28]	NK	C
Megestrol acetate[29-31]	NK	C
OTHERS		
Corticotropin or adrenocorticotropic hormone[32-37,c]	NK	A
γ-hydroxybutyric acid[25]	NK	C

NK = not known.

[a] Incidence depends on dose and duration of exposure.

[b] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[c] Used as a confirmatory test to stimulate cortisol release.

Table 32-2 Mechanisms of Drug-Induced Cushing Syndrome

Drug	Mechanism
Adrenocorticotropin hormone (corticotropin, ACTH)[41]	Stimulates cortisol release from the zona fasciculata of the adrenal cortex
γ-hydroxybutyric acid[25]	Stimulates ACTH release from the pituitary gland
Glucocorticoids[46]	Resemble the naturally occurring glucocorticoid, cortisol, and bind with high affinity to specific cytoplasmic glucocorticoid receptors Binding modifies transcription and causes changes in protein synthesis that can produce adverse physiologic effects
Progestins[29]	Possess glucocorticoid-like activity and can bind to the glucocorticoid receptors

ACTH = adrenocorticotropic hormone.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Signs and symptoms of drug-induced Cushing syndrome are summarized in **Table 32-3**.[41,43,44] Common findings include progressive adiposity, dermopathies, myopathy, hypertension, insulin resistance (and corresponding elevations in glucose), hyperlipidemia, psychiatric changes, osteoporosis, gonadal and thyroid dysfunction, and growth deceleration in children.[41,43,44] Some features, such as increased intraocular pressure, cataracts, osteoporosis, and pancreatitis may be more prevalent with drug-induced Cushing syndrome; while other features such as hypertension, hirsutism, and amenorrhea may be more prevalent with the other etiologies.[47]

The biochemical diagnosis of Cushing syndrome relies on two steps: (1) confirming the presence of hypercortisolism and (2) identifying the underlying etiology of hypercortisolism. Hypercortisolism can be established using one or more of the following: the 24-hour urinary free cortisol test, the midnight serum cortisol test, the late-night salivary cortisol test, or the low-dose dexamethasone-suppression test.[32-37] Elevated urinary free cortisol values four times the upper limit of normal, late-night salivary cortisol >250 ng/dL, midnight serum cortisol >7.5 mcg/dL, or morning serum cortisol after low-dose dexamethasone suppression test >1.8 mcg/dL strongly suggest Cushing syndrome.[32-37] Midnight serum cortisol is often considered to be a second-line test, because admission to the hospital for 48 hours prior to testing may be necessary to help avoid false positive responses secondary to the stress of hospitalization. An additional confirmatory test is the determination of the plasma ACTH concentration, where values <5 pg/mL confirm drug-induced Cushing syndrome.[32-37]

Table 32-3 Signs and Symptoms Associated with Drug-Induced Cushing Syndrome

Signs and Symptoms	Incidence[a]
Central obesity	95%
Moon-shaped face	90%
Thin skin	85%
Oligomenorrhea or amenorrhea	80%
Hirsutism	75%
Hypertension	75%
Psychiatric mood changes	70%
Easy bruising	65%
Diabetes	60%
Glucose intolerance	60%
Proximal muscle weakness	60%
Osteopenia or osteoporosis	50%
Acne	NK
Buffalo hump	NK
Glaucoma, increased ocular pressure	NK

Kyphosis	NK
Pancreatitis	NK
Striae	NK

NK = not known.

[a]Prevalence related to general Cushing syndrome.

The clinical manifestation of drug-induced hypercortisolism is often quite similar to endogenous causes of hypercortisolism, such as Cushing syndrome, thus requiring a careful history in combination with dynamic testing of the integrity of the HPA axis to arrive at a correct diagnosis. Drugs, stress, renal insufficiency, alcohol ingestion, obesity, pregnancy, sleep disorders, and psychiatric illness can interfere with the diagnostic tests, making it challenging to differentiate between the causes (**Table 32-4**).[32,36] Patients with drug-induced Cushing syndrome typically present with low 24-hour urinary free cortisol concentration, low serum cortisol concentration, and suppressed ACTH levels.[47] Other significant laboratory findings in these patients may include presence of synthetic glucocorticoids in the urine, elevation of total cholesterol, high concentrations of very-low-density lipoprotein and triglycerides, hypokalemia, and low bone density as measured by dual x-ray absorptiometry.[33,47]

Table 32-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Cushing Syndrome

- Alcohol abuse
- Diabetes mellitus (Type 2)
- Metabolic syndrome
- Nondrug-induced Cushing syndrome (e.g., Cushing syndrome)
- Obesity
- Pregnancy
- Psychiatric illness
- Renal insufficiency
- Sleep disorders
- Stress

RISK FACTORS

Risk factors for drug-induced Cushing syndrome are presented in **Table 32-5**.[43] Prolonged use, especially at a high dose, of any drug(s) that can cause Cushing syndrome is a known risk factor. Although inhaled, nasal, and topical glucocorticoids are intended to minimize systemic absorption, high doses and incorrect administration may result in increased absorption sufficient to cause Cushing syndrome.[1-18,43] High doses of drugs that possess glucocorticoid-like activity may enhance GR binding, as seen with oral progestins (e.g., 200–400 mg of MPA or 160 mg of megestrol acetate).[26-31] Additional risk factors for increased absorption of topical glucocorticoids include a broader area of coverage, high frequency of application, older patient age, and compromised skin integrity.[17,43,48]

Table 32-5 Risk Factors for Drug-Induced Cushing Syndrome

- Administration of drugs that inhibit the metabolism of glucocorticoids
- Administration of high doses of offending agent
- Prolonged duration of therapy
- Use of high-potency glucocorticoids
- Use of topical glucocorticoids in patients with broken or atrophic skin and in infants

Administration of high-potency glucocorticoids or drugs with a high affinity for GRs is another known risk factor for drug-induced Cushing syndrome. Of the available inhaled corticosteroids (ICS), fluticasone is considered the most potent, exhibiting prolonged drug retention at receptors in both blood and systemic tissues.[2,5] Clobetasol is one of the most potent topical glucocorticoids and, when used in high doses and for prolonged periods, has been reported to induce Cushing syndrome.[48,49]

Coadministration of potent inhibitors of the Cytochrome P450 (CYP450) isoenzyme family with glucocorticoids metabolized by these isoenzymes can lead to hypercortisolism via increased binding to the GRs. Cases of drug-induced Cushing syndrome have been reported when normal doses of inhaled fluticasone are coadministered with ritonavir and itraconazole, known inhibitors of fluticasone metabolism.[5,6,8-11] Cushingoid features also may develop in poor metabolizers of corticosteroids even when administering normal doses.[46]

MORBIDITY AND MORTALITY

Persons with overt but incompletely controlled endogenous Cushing syndrome have a fivefold increased risk of mortality relative to those with controlled Cushing syndrome.[45] Although the incidence of death due to drug-induced Cushing syndrome, per se, is unknown, it likely carries a lower risk than endogenous Cushing syndrome given that most cases are reversible following discontinuation of the causative agent. Cardiovascular complications have traditionally been regarded as the major contributor to morbidity and mortality in patients with Cushing syndrome and usually stem from uncontrolled blood pressure, glucose concentrations, and weight gain.[32,44] However, osteoporosis, fractures, thromboembolic events, and psychiatric illnesses are also common if hypercortisolism is not corrected.[32,44]

PREVENTION

Approaches to help prevent drug-induced Cushing syndrome are presented in **Table 32-6**. Minimizing the risk factors presented in Table 32-5 may prevent drug-induced Cushing syndrome.[43] When administering agents with the potential to induce Cushing syndrome, practitioners should make every effort to use the lowest effective dose for the shortest period of time. In addition, concurrent administration of agents that reduce glucocorticoid metabolism should be avoided.

Inhaled and intranasal glucocorticoid administration can minimize systemic absorption and may help prevent Cushing syndrome. Topical glucocorticoids can produce desired pharmacologic effects without associated systemic adverse effects, although caution is advised in patients with broken skin or when occlusive dressings are required. The administration of glucocorticoids in the form of enemas may obviate the need for systemic glucocorticoids in patients with inflammatory bowel disease. Practitioners should be aware of these and other alternatives to systemic glucocorticoid therapy.

Table 32-6 Approaches to Help Prevent Drug-Induced Cushing Syndrome

- Avoid drug–drug interactions (e.g., CYP inhibitors) that will increase plasma concentrations of the offending agent
- Use alternative route of administration to minimize systemic absorption
- Use lowest effective dose and avoid prolonged use of offending agent

MANAGEMENT

The first and most important step in managing drug-induced Cushing syndrome is discontinuation of the offending agent when feasible. If the patient has been receiving a supra-physiologic dose of glucocorticoids (>7.5 mg daily of prednisone or its equivalent), that dose must be slowly tapered to a physiologic dose, often over months, to avoid precipitating adrenal insufficiency. After a physiologic dose has been achieved, the patient should continue to have the dose slowly tapered until the HPA axis has returned to normal function, which may take up to 1 year. Morning serum cortisol may be used to test for HPA axis integrity. Glucocorticoid replacement may be discontinued when cortisol plasma concentration is >20 mcg/dL. In cases in which alternative therapy is not an option and continued steroid treatment is required, strategies to reduce inhibition of the HPA axis should be considered, including the use of alternate-day dosing schedules (e.g., alternating between "on" and "off" days), the use of a less potent glucocorticoid, and nonsystemic routes of administration.[30,32]

INFORMATION FOR PATIENTS

Patients receiving long-term glucocorticoid therapy by any route of administration should be informed about the signs and symptoms of Cushing syndrome and advised to contact their pharmacist or physician if any of these develop. Because development of Cushingoid features is often insidious, periodic review and comparison between old and new photographs can be helpful in identifying physical changes when Cushing syndrome is suspected. The potential dangers of using higher doses than prescribed should also be discussed with patients in an effort to prevent supra-physiologic concentrations of glucocorticoids. Patients should also be instructed not to abruptly discontinue glucocorticoid therapy to avoid occurrence of adrenal crisis that can be a life-threatening problem in patients who have suppression of the HPA axis. Appropriate medication administration instructions should also be provided to patients taking or using any corticosteroid preparation to help minimize systemic exposure. Consultation points can include proper inhaler technique and avoidance of applying topical corticosteroids to nonintact skin.

SECONDARY ADRENAL INSUFFICIENCY

Hypocortisolism is the hallmark of adrenal insufficiency, which can be separated into two categories: primary and secondary. Primary adrenal insufficiency, commonly referred to as Addison disease, is caused by the inability of the adrenal cortex to produce cortisol, aldosterone, and androgens while the preceding components of the HPA axis remain functional. Because of the reduced negative feedback on the hypothalamus and pituitary, CRH and ACTH plasma concentrations are elevated in primary adrenal insufficiency. Secondary adrenal insufficiency (SAI) often results from exogenous glucocorticoid use, which suppresses the HPA axis, decreases ACTH release, and impairs cortisol and androgen production. In SAI, CRH and ACTH concentrations are usually low and aldosterone production is typically preserved.

Primary and secondary adrenal insufficiency share many clinical features related to hypocortisolism. In primary adrenal insufficiency, increased CRH stimulates release of melanocyte-stimulating hormone. Both melanocyte-stimulating hormone and ACTH cause melanocytes to form melanin in the skin's epidermis, leading to hyperpigmentation, a characteristic trait of Addison disease. In addition, patients with primary adrenal insufficiency more commonly experience electrolyte abnormalities, especially hyperkalemia. These clinical findings are usually absent in drug-induced SAI.

CAUSATIVE AGENTS

Drugs that have been reported to suppress the HPA axis and cause SAI on discontinuation are listed in **Table 32-7**.[5,15-17,21,22,27-30,39-41,43,50-77] The most common cause of drug-induced SAI is exogenous glucocorticoid, with clinical manifestations of the disorder occurring on abrupt withdrawal of these agents. Medications used for the treatment of Cushing syndrome, including ketoconazole, etomidate, and mitotane, have also been implicated in drug-induced SAI.

EPIDEMIOLOGY

SAI has an overall estimated prevalence of 150–280 cases per 1 million persons.[78] Excessive glucocorticoid therapy induces atrophy of pituitary corticotroph cells and is thought to be the primary cause of this disorder, with an estimated prevalence of 20–50% among patients taking exogenous glucocorticoids for longer than 1 year.[79,80] Drug-induced SAI is usually only clinically relevant during or after glucocorticoid withdrawal, although a few other mechanisms have been identified (see below). Higher glucocorticoid doses administered over longer periods (>7.5 mg of prednisone or equivalent for >3 weeks) are often implicated in SAI, but patient response is highly variable, and HPA axis suppression may occur with any dose or duration of therapy.[43] As with Cushing syndrome, glucocorticoid administration via virtually any route may suppress the HPA axis.[5,15-17,21,22,41,43,50-58] In most patients, adrenal function returns to normal within 14 days after glucocorticoid withdrawal.[81] In a minority of patients with drug-induced SAI due to corticosteroid use, normalization of the adrenal gland may take up to 1 year.[43,82] In other drug-induced causes where the adrenocortical tissue is destroyed, hypofunction of the adrenal glands may be permanent.

MECHANISMS

Mechanisms of drug-induced SAI are listed in **Table 32-8**. Drug-induced SAI is characterized by a reduction in ACTH secretion from the pituitary gland, resulting in atrophy of the adrenal cortex. A low endogenous cortisol concentration is not clinically manifest if glucocorticoid activity is supplemented through exogenous glucocorticoid administration. However, when exogenous glucocorticoid therapy is abruptly stopped or when the patient is exposed to stressful stimuli (e.g., surgery, trauma, infection), adrenal suppression becomes clinically apparent because of the inability of the adrenal cortex to mount a sufficient cortisol response.

Sustained negative feedback activity on GRs in the anterior pituitary gland and hypothalamus, as occurs with high-dose and prolonged exogenous glucocorticoid administration, may lead to prolonged suppression of CRH, which in turn, suppresses ACTH release from the anterior pituitary and results in a lack of adrenal secretion of cortisol.[41,78,83]

Numerous studies have documented the ability of inhaled and nasal glucocorticoids to suppress the HPA axis, especially when administered in high doses or when combined with inhibitors of CYP450 3A4.[5,50-57,84] At recommended doses, however, inhaled and nasal glucocorticoids rarely suppress adrenal function. Topical, intra-articular, intradermal, intramuscular, intralesional, and paraspinal administration of glucocorticoids have also been implicated in SAI.[15-17,21,22,58] Patients with compromised skin integrity who use high-potency topical glucocorticoids (e.g., clobetasol propionate) may be at higher risk for SAI.[15-17,49,58]

Table 32-7 Agents Implicated in Drug-Induced Adrenal Insufficiency

Drug	Incidence[a]	Level of Evidence[b]
ORAL GLUCOCORTICOIDS		
Dexamethasone[50]	83%	A
Prednisone[50]	80%	A
INHALED GLUCOCORTICOIDS		
Beclomethasome dipropionate[3,53]	NK	B
Budesonide[3,51]	NK	B
Fluticasone propionate[3,5,6,39,46]	NK	B
Mometasone furoate[7]	NK	B
Triamcinolone acetonide[3]	NK	B
NASAL GLUCOCORTICOIDS		
Beclomethasome dipropionate[56]	NK	C
Fluticasone propionate[5,50]	NK	C
TOPICAL GLUCOCORTICOIDS

Mitotane[68,c]	NK	C
Rifampin[70,71]	NK	C

NK = not known.

[a] Incidence depends on dose and duration of exposure.

[b] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[c] Used as medical treatment for hypercortisolism.

[d] Not approved for use in the United States, but it is sometimes acquired illegally for recreational use.

When administered at high doses, progestins or progestin analogs also may suppress the HPA axis. These agents, specifically MPA and megestrol acetate, possess glucocorticoid-like activity thought to be due to existing cross-reactivity within this family of steroid receptors.[27,30,59-62] Ketoconazole, etomidate, mitotane, and other agents used to treat Cushing syndrome interfere with cortisol synthesis leading to lower circulating endogenous cortisol.[41,63-69] Mitotane also possesses cytotoxic properties and can cause atrophy of the adrenal cortex, mostly affecting the zona fasciculata and zona reticularis.[41] Thus, production of endogenous cortisol and sex hormones may be affected, while production of aldosterone is usually spared.[85] Rifampin, phenytoin, and phenobarbital may suppress the axis by inducing

CYP450 isozymes responsible for cortisol metabolism.[41,70,71] Mirtazapine appears to cause adrenal suppression by antagonizing central 5-hydroxytryptamine$_2$ receptors responsible for the stimulation of cortisol secretion.[72] Opioids inhibit CRH release by binding to hypothalamic δ- and κ-opiate receptors.[73,74] Certain benzodiazepines may inhibit pituitary response to CRH.[75]

Table 32-8 Mechanisms of Drug-Induced Secondary Adrenal Insufficiency

Drug	Mechanism
Etomidate[66]	Inhibits 17α-hydroxylase and 11α-hydroxylase, resulting in reduced cortisol synthesis
Fentanyl[74] Flunitrazepam[75]	Inhibit pituitary response to CRH
Glucocorticoids[78,83]	Sustained stimulation of the negative feedback effect on GRs in the anterior pituitary gland and hypothalamus leads to prolonged suppression of CRH, which in turn suppresses ACTH release from the anterior pituitary and results in a lack of adrenal secretion of cortisol. This process is also referred to as suppression of the HPA axis.
Hydromorphone[73]	Inhibits CRH release through binding to hypothalamic 6- and n-opiate receptors
Ketoconazole[63,64]	Inhibits cholesterol side-chain cleavage and cytochrome P450 enzymes, 17α-hydroxylase and 17,20-lyase, resulting in reduced cortisol synthesis
Mirtazapine[72]	Antagonizes central 5-hydroxytryptamine$_2$ and/or histamine$_1$ receptors, resulting in decreased CRH release, ACTH secretion, and cortisol release
Mitotane[41,68]	Inhibits 11α-hydroxylase, 18-hydroxylase, 3α-hydroxylase, and cholesterol side-chain cleavage, resulting in reduced cortisol synthesis Degenerates cells within the zona fasciculata and reticularis; the zona glomerulosa can be affected with long-term treatment
Progestins[59,61]	Suppress HPA through their ability to bind to the GR
Rifampin[70,71]	Induces cytochrome P450 isoenzymes responsible for cortisol metabolism

ACTH = adrenocorticotropic hormone, CRH = corticotropin-releasing hormone, GR = glucocorticoid receptor, HPA = hypothalamic–pituitary–adrenal.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Signs and symptoms associated with drug-induced SAI are presented in **Table 32-9**.[77,78,82,83,86] Patients may present with abnormal laboratory values such as hyponatremia, hypoglycemia, mild normocytic anemia, lymphocytosis, and mild eosinophilia. **Table 32-10** lists conditions that must be considered in the differential diagnosis of drug-induced SAI.[78] Rarely, acute adrenal insufficiency may be life-threatening. Patients with this disorder may exhibit severe hypotension or hypovolemic shock, hypoglycemia, acute abdominal pain, vomiting, and fever.[82,86]

The laboratory diagnosis of adrenal insufficiency involves measurement of early morning plasma cortisol concentration as well as dynamic testing.[77-79,82,86] Adrenal insufficiency can be ruled out by measuring a plasma cortisol concentration between 7 and 9 a.m. A concentration of <3 mcg/dL (100 nmol/L) is indicative of adrenal insufficiency, and a concentration of >18 mcg/dL (500 nmol/L) rules out the disorder.[77,78,87] Dynamic testing is required for patients with a cortisol concentration between 3 and 18 mcg/dL and can be useful in determining the cause of the disease. Dynamic tests include the insulin-tolerance test, metyrapone test, ACTH stimulation test, and CRH stimulation test.[77-79,82,83,86,88]

The insulin-tolerance test is considered the standard for the evaluation of SAI because hypoglycemia in normal subjects results in rapid activation of the HPA axis.[77,78,83,88] This test is labor-intensive, with patients requiring constant supervision by a medical professional because a serum glucose of <40 mg/dL and symptoms of hypoglycemia are required elements of the test. The insulin-tolerance test is contraindicated in patients >60 years of age, those with cardiovascular disease, and those with a history of seizures.[77,78] An ACTH stimulation test is often preferred because of its ease of use and relatively high correlation with the insulin-tolerance test. Patients are given 250 mcg of synthetic ACTH (cosyntropin) intravenously or intramuscularly, and serum cortisol concentrations are measured at baseline and 60–90 minutes after the injection. An increase in the cortisol concentration to >18 mcg/dL at 60–90 minutes rules out adrenal insufficiency. In several studies, doses of 0.5 mcg or 1 mcg instead of the customary 250 mcg dose of synthetic ACTH have been effective in stimulating a cortisol response and are associated with higher sensitivity in identifying patients with subtle SAI. Because cortisol secretion can vary throughout the day, the test should ideally be done in the morning to ensure optimal sensitivity and specificity.[89] Studies also suggest that cortisol concentrations should be obtained at 30–60 minutes for the low-dose test.[77-79,82,83] The CRH stimulation test also correlates well with the insulin-tolerance test in patients with SAI, but it is less standardized and is costly.[77-79,82,83]

Table 32-9 Signs and Symptoms Associated with Drug-Induced Secondary Adrenal Insufficiency

Signs and Symptoms	Incidence[a]

Weakness or fatigue	100%
Weight loss or anorexia	100%
Hypotension or postural hypotension	88–94%
Gastrointestinal symptoms (abdominal cramps, nausea, diarrhea, vomiting)	92%
Hyponatremia	88%
Myalgia or arthralgia	6–13%
Anemia, lymphocytosis, eosinophilia	NK
Hypoglycemia	NK
Vitiligo	NK

NK = not known.

[a] Prevalence related to general adrenal insufficiency.

Table 32-10 Conditions to Consider in the Differential Diagnosis of Drug-Induced Secondary Adrenal Insufficiency

- Addison disease
- Anemia
- Chronic fatigue syndrome
- Chronic heart failure
- Liver disease
- Myopathies
- Neuropsychiatric weakness
- Pigmentation disorders
- Syndrome of inappropriate antidiuretic hormone

RISK FACTORS

Specific risk factors associated with drug-induced SAI are presented in **Table 32-11**.[3,41,43,49,82,90] Because this disorder is often a result of the exogenous administration of glucocorticoids, risk factors for SAI and Cushing syndrome are very similar; however, differences exist in terms of the precipitating event (e.g., continued use versus abrupt withdrawal of corticosteroids) that leads to the clinical syndrome.

In contrast to the use of standard doses, administration of high doses of inhaled and intranasal glucocorticoids have been associated with a higher incidence of adrenal suppression.[4,51,52,55-57] Specifically, ICSs such as beclomethasone dipropionate, budesonide, and triamcinolone acetonide at doses >1.5 mg/day and fluticasone propionate at a dose >0.75 mg/day caused marked adrenal suppression.[3] Likewise, topical glucocorticoids administered at high doses are associated with a higher risk of adrenal suppression.[49]

Table 32-11 Risk Factors for Drug-Induced Secondary Adrenal Insufficiency

- In the setting of abrupt glucocorticoid withdrawal
    - Administration of high doses
    - Prolonged duration of therapy
    - Use of high-potency glucocorticoids
    - Administration of drugs that inhibit the metabolism of endogenous and exogenous glucocorticoids
- Concomitant diseases (e.g., hypothyroidism, acquired immunodeficiency syndrome)
- Physical stress (stressful situation, surgery, infection, trauma)

High levels of systemic absorption can contribute to adrenal suppression with glucocorticoids, and the degree of CRH suppression is proportional to the amount of circulating cortisol or cortisol-like compounds. Because of rapid and extensive systemic absorption, the long-term (>3 week) use of oral glucocorticoids may induce significant adrenal suppression regardless of the dose administered.[43,49,82] ICSs are intended to limit systemic absorption through local deposition in the lung and high first-pass metabolism of any swallowed drug. However, 60% to 90% of the ICS dose may be swallowed and available for gastrointestinal absorption, and systemic absorption of small ICS particles may occur via lung alveoli.[91] Therefore, the risk of SAI from ICSs with high first-pass metabolism (e.g., fluticasone, mometasone) may be increased with drugs that inhibit the metabolism of glucocorticoids (e.g., ketoconazole, ritonavir) and when step-down therapy is not practiced following the reversal of airflow obstruction and inflammation.

Use of high-potency glucocorticoids increases the risk of drug-induced SAI. A list of commonly used orally administered glucocorticoids, according to relative potency, can be found in **Table 32-12**. In a meta-analysis of 21 studies examining ICS potencies, inhaled fluticasone exhibited significantly greater dose-related adrenal suppression as compared with inhaled beclomethasone, budesonide, or triamcinolone.[3] In another study, inhaled mometasone showed similar adrenal suppression at medium and high doses as compared with inhaled fluticasone.[92] Levin and Maibach identified the use of high-potency topical glucocorticoids such as clobetasol propionate as a risk factor for mild or reversible adrenal suppression.[58] Other risk factors for SAI associated with topical administration of glucocorticoids include prolonged duration of treatment, use on thin or damaged skin, and use in children and infants.[58]

Table 32-12 Pharmacologic Characteristics of Orally Administered Glucocorticoids

Glucocorticoid	Relative Anti-inflammatory Potency	Dose Equivalent (mg)	Approximate Half-Life (min)
LOW POTENCY			
Cortisone	0.8	25	30
Hydrocortisone	1	20	90
MEDIUM POTENCY			
Prednisone	3.5	5	60
Prednisolone	4	5	200
Triamcinolone	5	4	300
Methylprednisolone	5	4	180
HIGH POTENCY			
Betamethasone	25	0.6	100–300
Dexamethasone	30	0.75	100–300

Most cases of adrenal crisis in those with chronic SAI occur because of reduction of the glucocorticoid dose or as a result of failure to adjust glucocorticoid-replacement doses properly in the presence of stressors.[78] Concomitant diseases (e.g., hypothyroidism, acquired immunodeficiency syndrome) may impair the central response to stress and cortisol secretion and are also risk factors for the development of adrenal insufficiency.[86]

MORBIDITY AND MORTALITY

As discussed above, drug-induced SAI is accompanied by a constellation of nonspecific and usually non-life-threatening symptoms such as fatigue, anorexia, asthenia, weight loss, abdominal pain, nausea, vomiting, and weakness. However if unrecognized and untreated, SAI can be a fatal disorder because of the risk of circulatory collapse.[86]

PREVENTION

Methods to prevent drug-induced secondary adrenal insufficiency are presented in **Table 32-13**. Drug-induced SAI may be prevented by minimizing the risk factors associated with drug-induced adrenal insufficiency (Table 32-11). Practitioners should make an effort to use the lowest possible dose of agents that are known to suppress the HPA axis. This can be accomplished by using a step-down approach when symptoms resolve and by not exceeding the dose limits for the selected agent.

Table 32-13 Approaches to Help Prevent Drug-Induced Adrenal Insufficiency

- Avoid abrupt withdrawal of glucocorticoids (e.g., nonadherence, quick dose tapers upon discontinuation)
- Avoid drug–drug interactions (e.g., CYP inducers) that will decrease concentrations in patients on therapy with corticosteroids
- Double or triple oral glucocorticoid dose during times of severe physical stress (e.g., febrile illness or injury, surgery)
- Use topical or inhaled agents, as appropriate to minimize glucocorticoid systemic absorption
- Use a spacer to minimize swallowed glucocorticoid after metered-dose inhaler
- Use lowest effective dose of offending agent
- Use step-down therapy with inhaled corticosteroid after pulmonary obstruction and inflammation subside

Because glucocorticoid requirements are increased during times of stressful events, patients should be instructed to double or triple their oral glucocorticoid dose during febrile illness or injury. Patients may also be supplied with and instructed regarding the proper use of hydrocortisone intramuscular injections for emergency use. In some nonsevere cases where patients are experiencing nausea or vomiting, the glucocorticoid can be given in the form of rectal suppositories.[78,93]

The use of a spacer attached to a metered-dose inhaler may reduce the amount of drug that is swallowed and therefore decrease gastrointestinal absorption,[89] particularly for ICSs with lower first-pass metabolism. For higher-potency ICSs (e.g., fluticasone), appropriate administration, use of a spacer, and using the lowest possible maintenance dose may help reduce the risk of SAI.[91]

MANAGEMENT

Because drug-induced SAI is often due to the inappropriate withdrawal of glucocorticoids, replacement with glucocorticoids is generally the treatment of choice to correct the resultant adrenal crisis. In other cases of drug-induced SAI, identification of the offending medication is usually the first step, and discontinuation of the offending medication or substitution of an appropriate therapeutic alternative should be considered. In patients with chronic SAI or in those where discontinuation of the offending medication is not possible, treatment should be guided by replacement with physiological doses of glucocorticoids (**Table 32-14**).

Table 32-14 Management of Drug-Induced Secondary Adrenal Insufficiency

- Discontinue offending agent and initiate appropriate therapeutic alternative
- Taper slowly, if necessary, depending on agent being discontinued (e.g., glucocorticoids, progestins)
- If glucocorticoid replacement is required, the usual dose of hydrocortisone is 15–20 mg/day and that of prednisone 5–7.5 mg/day (one half to two thirds of the dose may be given in the morning)

Glucocorticoid replacement usually involves the administration of two or three daily doses. On average, the healthy adult produces approximately 10–30 mg of cortisol per day, with the peak concentration occurring around 8:00 a.m. This cortisol concentration is equivalent to approximately 15–20 mg of hydrocortisone or 5–7.5 mg of prednisone every day. One half to two thirds of the dose may be given in the morning to mimic the normal diurnal variation of cortisol.[78,92] Hydrocortisone and prednisone are preferred over agents with longer half-lives, such as prednisolone, triamcinolone, dexamethasone, and betamethasone, because the former agents may allow the HPA axis more opportunity to recover and appropriately release CRH and ACTH based on the body's need for cortisol.[43,78,82,86]

Minor abnormalities discovered on dynamic testing should be treated only in the presence of symptomatic adrenal insufficiency. Testing should be performed on any patient who reports suggestive symptoms or on any child whose growth velocity is slowed. The lowest effective dose of glucocorticoid should be used, and dosing should be guided by symptomatic management of fatigue and other symptoms as described in Table 32-9.[77,78,93]

Because suppression of the HPA axis is a major concern only when exogenous glucocorticoids are withdrawn, practitioners should avoid abruptly stopping oral glucocorticoids taken for longer than 14 days. A variety of recommendations for steroid tapering are available; however, no consensus exists regarding the best approach.[41,43] In general, for patients who have been taking long-term steroid therapy, the steroid should be gradually withdrawn toward physiologic doses over months. As the steroid dose approaches physiologic levels, the taper should be slowed and the patient monitored for HPA axis function. The primary modes to test HPA axis integrity are the ACTH test, either high- or low-dose, or measurement of a morning serum cortisol level.[41,43] A normal morning serum cortisol concentration (>20 mcg/dL) or a normal ACTH test indicates that daily steroid maintenance therapy is not needed. If the morning serum cortisol concentration is between 3 and 20 mcg/dL, an ACTH test or an CRH stimulation test may be useful in the assessment of pituitary–adrenal function.[43] A morning cortisol concentration <3 mcg/dL indicates axis suppression and the need for continued replacement therapy. Caution should be used to prevent disease exacerbation during the steroid taper and the resultant need to treat the patient with another course of high-dose corticosteroids.[41]

Adrenal crisis has been reported after the discontinuation of MPA and megestrol acetate; therefore, tapering is also recommended for patients receiving these agents. Although adrenal suppression can occur in patients receiving inhaled, intranasal, and topical glucocorticoids, supplementation during periods of stress and/or tapering of doses prior to complete discontinuation is usually not needed.[58] Due to the direct cytotoxic effects on the adrenal cortex, therapy with mitotane may require replacement with both glucocorticoids and sex hormones, although data regarding management of mitotane-induced adrenal insufficiency are sparse.[85]

INFORMATION FOR PATIENTS

Patients receiving long-term inhaled, topical, and oral glucocorticoids should be educated regarding the signs and symptoms associated with SAI and instructed to contact their healthcare provider if these develop. The importance of adherence to long-term therapy with glucocorticoids should be addressed with patients in an effort to prevent any abrupt withdrawal leading to adrenal crisis. Patients should carry an information card with details about their current treatment and instructions for emergency treatment, including instructions on doubling or tripling the glucocorticoid dose during febrile illness or injury and using alternative routes of administration during vomiting.[77,78,93] Patients should be instructed to rinse their mouth after administration of an ICS to minimize side effects (e.g., thrush, hoarseness) as well as to decrease systemic absorption from oropharyngeal deposition. Lastly, patients should be educated to not use topical glucocorticoids on thin skin areas (e.g., eyelid, scrotum), on broken skin, or over large surface areas.

DRUG-INDUCED HYPERPROLACTINEMIA

The regulation of prolactin is unique among the anterior pituitary hormones. Prolactin is regulated through hypothalamic inhibition, with dopamine as the main inhibitory factor. As a result, drug-induced hyperprolactinemia may occur with any drug that inhibits the action of dopamine in the central nervous system.

CAUSATIVE AGENTS

Specific drugs that have been reported to induce hyperprolactinemia are listed in **Table 32-15**.[94-147] Conventional first-generation antipsychotics have been frequently associated with drug-induced hyperprolactinemia. Atypical, or second-generation, antipsychotics were developed to minimize side effects seen with first-generation antipsychotics; however, these medications are still associated with some risk for hyperprolactinemia. Risperidone is known to cause hyperprolactinemia more frequently than other atypical antipsychotics. Additional medications that have been implicated in causing hyperprolactinemia include antidepressants, antihypertensive agents, and gastrointestinal motility drugs.

EPIDEMIOLOGY

Hyperprolactinemia is the most common endocrine disorder of the HPA axis, with an estimated prevalence of 0.4% in the normal adult population and as high as 9% among women with amenorrhea.[148] The prevalence is approximately 5% among men presenting with impotence. The highest prevalence is among women with amenorrhea and galactorrhea, at 70%.[148] The incidence of drug-induced hyperprolactinemia is unknown.

MECHANISMS

Mechanisms of drug-induced hyperprolactinemia are listed in **Table 32-16**. Prolactin secretion by the lactotroph cells of the anterior pituitary is controlled by the inhibitory effect of the hypothalamus through one or more prolactin inhibitory factors (PIFs). Dopamine is the main physiologic PIF; therefore, any drug that is associated with inhibition of dopamine release or action can induce hyperprolactinemia. Antipsychotics and antiemetics with strong dopamine-receptor (D_2) blockade such as the phenothiazine derivatives, haloperidol, and metoclopramide work through this mechanism and have traditionally been reported to cause hyperprolactinemia.[94-97,107-109,116-125,136,147,149]

Serotonin is a strong stimulator of prolactin secretion; therefore, antidepressants that inhibit the reuptake or breakdown of serotonin can increase prolactin concentration.[94-106,147] Antihypertensives such as methyldopa and reserpine stimulate prolactin secretion by negating dopaminergic inhibition, whereas hormones such as estrogen appear to promote prolactin secretion by stimulating lactotroph growth.[94-97,110,111,126] Verapamil is believed to cause hyperprolactinemia by decreasing dopaminergic activity through blockade of N-type calcium channels in the cell membranes of neurons in the tuberoinfundibular dopaminergic tract.[94,97,113,145] Although protease inhibitors have been identified as a possible direct cause of hyperprolactinemia, the condition is most likely due to concomitant use of antiemetics or the presence of infection in patients receiving protease inhibitors.[134-137]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The most common symptoms associated with hyperprolactinemia typically are related to sexual dysfunction and may be difficult to recognize.[150] In men, these symptoms may include decreased libido, impotence, and erectile dysfunction; whereas in women, symptoms include menstrual disorders and galactorrhea.[97,148-151] Sustained hyperprolactinemia can also be associated with increased risk of pituitary tumors and breast cancer, although the exact causal relationship is currently unknown.[149,150] Due to prolonged disruption of the hypothalamic-pituitary-gonadal axis, chronic hyperprolactinemia may also lead to decreased bone mineral density.[149,150] Signs and symptoms associated with hyperprolactinemia are presented in **Table 32-17**.[92,97,148-152]

Table 32-15 Agents Implicated in Drug-Induced Hyperprolactinemia

Drug	Incidence	Level of Evidence[a]
ANTIDEPRESSANTS

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Not approved for use in the United States.

[c] Incidence depends on dose.

Table 32-16 Mechanisms of Drug-Induced Hyperprolactinemia

Drug	Mechanism
Alcohol[138]	Stimulates the release of prolactin possibly through a decreased inhibitory effect of dopamine
Antidepressants[100,101,147]	Serotonin is a strong stimulator of prolactin secretion Antidepressants inhibit the reuptake or breakdown of serotonin
Antiemetics[94,97,107,147] Antipsychotics[94,97,116,147] Methyldopa[94,97,110,147] Reserpine[94,97,112]	Prolactin's secretion is controlled by the inhibitory effect of the hypothalamus through one or more prolactin inhibitory factors Dopamine is the main physiologic prolactin inhibitory factor Any drug that is associated with inhibition of dopamine production (e.g., methyldopa), release (e.g., reserpine), or action (e.g., antiemetics, antipsychotics) can induce hyperprolactinemia
Antiretrovirals[134,135]	Most likely due to concomitant antiemetics or concurrent infection
Estrogens[94,97,126,145]	Increase the number of prolactin-secreting cells in the pituitary
Gonadotropin-releasing hormone analogs[127,128]	Decrease in the release of hypothalamic prolactin inhibitory factors
H_2-receptor antagonists[130,131]	Unknown centrally mediated prolactin release
Opioids[132,133,145]	Bind to μ-opioid receptors that may inhibit hypothalamic dopamine secretion
Tetrahydrocannabinol[144]	Stimulates the release of prolactin possibly through a decreased inhibitory effect of dopamine
Verapamil[94,97,113,145]	Decreases dopaminergic activity by blocking N-type calcium channels

The diagnosis of hyperprolactinemia requires two or more serum prolactin concentrations above 20 mcg/L (424 mU/L) in males and 25 mcg/L (530 mU/L) in females in combination with symptoms. However, as in drug-induced Cushing syndrome, determining the cause can prove challenging. A thorough and careful medication history will help identify possible drug-related causes of hyperprolactinemia, and an evaluation of thyroid, kidney, and liver function is essential to rule out elevated prolactin concentrations secondary to organ dysfunction (**Table 32-18**).[96,97,148,151] The severity of hyperprolactinemia also can be useful in determining the cause. In drug-related hyperprolactinemia, serum prolactin concentrations rarely exceed 100 mcg/L, whereas serum prolactin concentrations exceeding 200 mcg/L are almost always associated with pituitary macroadenomas.[96,97,148,151] An elevated prolactin concentration can also be seen in the presence of macroprolactinemia, an immune complex formed by immunoglobulin G and prolactin.[152] This condition must be ruled out, as this abnormality is found in 10% of patients with hyperprolactinemia.[96] Macroprolactinemia is often asymptomatic, and the need for treating asymptomatic patients is controversial.[153]

Table 32-17 Signs and Symptoms Associated with Drug-Induced Hyperprolactinemia

Signs and Symptoms	Incidence
MEN	
Gynecomastia	1–11%
Erectile dysfunction	NK
Decreased body hair	NK
WOMEN	
Oligomenorrhea or amenorrhea	40–50%
Hirsutism	NK
MEN AND WOMEN	
Osteoporosis	57% men, 32% women
Galactorrhea	20%
Decreased libido	NK
Infertility	NK
Weight gain	NK

NK = not known.

Table 32-18 Conditions to Consider in the Differential Diagnosis of Drug-Induced Hyperprolactinemia

- Acromegaly
- Breast stimulation
- Chest wall trauma and surgery
- Cirrhosis
- Excessive exercise
- Hypothyroidism
- Macroprolactinemia
- Nonfasting blood sample used for determination of prolactin concentration
- Polycystic ovarian syndrome
- Postictal (1–2 hours after seizure) prolactin elevation
- Pregnancy or postpartum prolactin elevation
- Prolactin-secreting adenomas

- Renal failure
- Sexual activity

Table 32-19 Risk Factors for Drug-Induced Hyperprolactinemia and Growth Hormone Deficiency

Hyperprolactinemia

- Administration of high doses of offending agent
- Female sex
- Use of potent D_2-receptor antagonists

Growth hormone deficiency

- Development of Cushing syndrome (see Table 32-5)
- Family history

RISK FACTORS

Risk factors associated with drug-induced hyperprolactinemia are presented in **Table 32-19**.[94,96,97,148,149,151] The highest risk for developing drug-induced hyperprolactinemia is associated with the use of potent D_2 receptor antagonists such as conventional antipsychotics, risperidone, and the antiemetics—metoclopramide and domperidone.[97,149,152] Although the dose of antipsychotic drugs has been correlated with prolactin levels in some studies, others have shown a tolerance to drug effects over time with normalizing prolactin levels.[149] Higher doses of drugs that potentiate prolactin via alternative mechanisms (e.g., estrogen, antidepressants) are probably needed to induce hyperprolactinemia.[97,151]

MORBIDITY AND MORTALITY

The incidence of death due to drug-induced hyperprolactinemia is unknown. Spontaneous galactorrhea, amenorrhea, gynecomastia in men, and sexual dysfunction may lead to embarrassment and reduced quality of life.[97,150] Osteoporosis is a long-term consequence that may lead to fracture, and certain fractures (e.g., hip) may increase the risk of death. Other potential long-term consequences of drug-induced hyperprolactinemia include pituitary tumors, breast cancer, venous thromboembolism, and depression.[97,149,150] Most, if not all, symptoms resolve when prolactin levels return to normal.[97]

PREVENTION

Methods to prevent drug-induced hyperprolactinemia are presented in **Table 32-20**. Drug-induced hyperprolactinemia may be prevented by minimizing the risk factors associated with hyperfunction of the hypothalamus, adrenal, or pituitary glands. When agents that can potentially induce hyperprolactinemia must be used, practitioners should make an effort to use the lowest effective dose of these agents, particularly with the D_2 antagonists. Effective therapy can be achieved by using a stepwise approach in the management and administration of these agents, starting with a low dose and titrating up to the desired effect or decreasing the dose if adverse effects occur. In addition, agents that interact pharmacokinetically (e.g., inhibit metabolism) with drugs known to cause hyperprolactinemia should be avoided.

Table 32-20 Approaches to Help Prevent Drug-Induced Hyperprolactinemia

- Avoid drug interactions that increase plasma concentrations of the offending agent
- Avoid drugs that exert potent D_2-receptor antagonism
- Use lowest effective dose of offending agent

MANAGEMENT

Management of drug-induced hyperprolactinemia requires recognition of the causative agent(s). Once a drug has been identified as the cause, the logical first step is to attempt to discontinue the offending medication and replace it with an appropriate alternative. Problems can arise, however, when the patient is well controlled with the offending agent and alternatives are not available, which is often the case with conventional or first-generation antipsychotics. In these cases, changing to an antipsychotic with less potential to cause drug-induced hyperprolactinemia (e.g., olanzapine, quetiapine, aripiprazole, clozapine) is perhaps the most appropriate option, as administration of a dopamine agonist may worsen psychiatric symptoms.[97,149] If maintaining the offending agent is the only option, initiating a dopamine agonist and, in those who require it (e.g., patient with estrogen deficiency), sex-steroid replacement are options.[94,97,148,149,153] Pharmacologic sex-steroid monotherapy may be the safest option for patients treated with antipsychotics.

The greatest evidence for the effectiveness of dopamine agonist use in patients with hyperprolactinemia exists for the ergot derivatives, such as bromocriptine and cabergoline.[153] However, these agents may increase the risk of exacerbation of underlying psychosis and should be used cautiously in patients managed with antipsychotics.[145,150] Risk of cardiac valvulopathy is also a concern with these ergot derivatives; however, this risk is most evident during the treatment of Parkinson disease, where larger doses are typically used.[154] Pramipexole and ropinirole are nonergot derivatives that may possess a safer cardiac profile; however, very limited data exist for their use in the treatment of hyperprolactinemia.[153] Treatment options for hyperprolactinemia are presented in **Table 32-21**.

INFORMATION FOR PATIENTS

Patients receiving antipsychotic therapy should be provided information regarding the risks of elevated prolactin such as osteoporosis, reduced fertility, and sexual dysfunction.[155] Patients' concerns may be alleviated through appropriate education that these side effects typically subside once the offending agent is discontinued or switched to an acceptable alternative agent. When discontinuing the offending antipsychotic or initiating treatment with dopamine agonists, patients should be aware that their psychotic symptoms may worsen, and closer monitoring may be warranted during this period. Women should also be informed that dopamine agonists may restore fertility and appropriate contraceptive precautions should be used if pregnancy is not desired.[97,151] Finally, patients should be warned of common adverse effects associated with dopamine agonists, including nausea, insomnia, somnolence, peripheral edema, and orthostatic hypotension.[153]

Table 32-21 Management of Drug-Induced Hyperprolactinemia

- Discontinue offending agent
- Initiate appropriate therapeutic alternative
- Consider initiation of dopamine agonist
    - Bromocriptine (2.5–10 mg/day)[a]
    - Cabergoline (0.25–1 mg/wk)[a]
    - Pramipexole[b]
    - Ropinirole[b]
    - Pergolide[c]
- Consider sex-steroid replacement in patients who require it
    - Testosterone
    - Estrogen
- Consider a bisphosphonate if low bone mineral density is found

[a] U.S. Food and Drug Administration–approved indication for hyperprolactinemia.

[b] Limited evidence of effectiveness.

[c] Not approved for use in the United States.

GROWTH HORMONE DEFICIENCY

Growth hormone (GH) is synthesized, stored, and released from somatotropes located in the anterior pituitary. GH secretion is mainly under the control of two hypothalamic peptides: GH-releasing hormone (GHRH) and somatostatin, also known as somatotropin-release–inhibiting factor (SRIF) or GH-inhibiting hormone (GHIH).[156,157] The secretion of GH is different from that of most other hormones in that it is released in a pulsatile fashion. This timing of release often complicates the diagnosis of GH deficiency, and provocative testing is required for accurate diagnosis.

CAUSATIVE AGENTS

Specific drugs that have been reported to cause GH deficiency are listed in **Table 32-22**.[41,156-168] Glucocorticoids play a prominent role in the regulation of GH secretion and thus may be the most common agents implicated in drug-induced GH deficiency. Other drugs that have been found to cause GH deficiency include phentolamine, isoproterenol, somatostatin analogs such as octreotide, and tyrosine kinase (TK) inhibitors such as imatinib.

EPIDEMIOLOGY

The frequency of drug-induced GH deficiency in the general population is unknown but is assumed to be rare. The average annual incidence of GH deficiency from any cause is approximately 1.76 per 100,000 persons as reported in a nationwide study from Denmark.[169] The most common cause of GH deficiency is a pituitary adenoma.[169,170]

MECHANISMS

Mechanisms for drug-induced GH deficiency are listed in **Table 32-23**. Inhibition of GH secretion by α- and β-adrenergic agonists may be mediated by an increase in SRIF secretion; however, β-adrenergic agonists may also reduce the GH response to GHRH.[156,158] Glucocorticoid excess increases hypothalamic secretion of somatostatin by enhancing responsiveness, thus inhibiting GH release from the pituitary.[167,171] In addition, chronic use of glucocorticoids can decrease the number of GH receptors leading to reduced tissue response to GH.[162,171] Gonadotropin-releasing hormone agonists used to treat precocious puberty and hormone-responsive cancers decrease hormone release from the pituitary.[161,165] Gonadotropin-releasing hormone is normally released in a pulsatile fashion;

however, continuous administration of these hormone agonists downregulates pituitary receptors, ultimately decreasing sex hormone and GH release.[41] Methylphenidate has a potent effect to alter the dopaminergic pathways involved in the regulation of GH secretion.[172] However, the effect of methylphenidate and amphetamines on the GH axis has been a matter of controversy, with some studies reporting inhibition, some no change, and some even reporting stimulation of GH secretion.[163] TK is involved in the complex signal transduction for GHRH in somatotropes to promote the secretion of GH.[173] In the peripheral tissues, TK also assists in the activation of cellular pathways to promote the actions of GH.[174]

Table 32-22 Agents Implicated in Drug-Induced Growth Hormone Deficiency

Drug	Incidence[a]	Level of Evidence[b]
Amphetamine derivatives[c]		
Methylphenidate[163]	NK	C
Dextroamphetamine[164]	NK	C
Glucocorticoids[159,171]	Variable	B
GnRH agonists[161,d]	NK	B
Isoproterenol[158]	NK	B
Phentolamine[158]	NK	B
Somatostatin analogs[160]	NK[e]	B
Tyrosine kinase inhibitors[168]	NK	C

GnRH = gonadotropin-releasing hormone, NK = not known.

[a] Incidence depends on dose and duration of exposure.

[b] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[c] Studies report inhibition, no change, and even stimulation of GH secretion.

[d] After repeated dosing.

[e] Unknown incidence due to use in patients with growth hormone excess.

Table 32-23 Mechanisms of Drug-Induced Growth Hormone Deficiency

Drug	Mechanism

α-adrenergic antagonists[156,158]	May decrease secretion of GH-releasing factor
Amphetamine derivatives[157]	Possibly decreases GH release through dopaminergic effects May decrease sleep-related GH release
β-adrenergic agonists[156,158]	May increase secretion of somatostatin or GH-inhibiting factor May also reduce the GH response to GH-releasing hormone
Glucocorticoids[162,166,167,171]	Increase hypothalamic secretion of somatostatin by enhancing β-adrenergic responsiveness, thus inhibiting GH release from the pituitary Reduce the number of GH receptors in tissue
GnRH agonists[161,165]	Continuous administration downregulates pituitary receptors ultimately decreasing GH release
Somatostatin analogs[156,157]	Directly inhibit GH release from the pituitary
Tyrosine kinase inhibitors[168]	May inhibit release of GH from somatotropes in the anterior pituitary May also attenuate response of GH on peripheral tissues

GH = growth hormone, GnRH = gonadotropin-releasing hormone.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Signs and symptoms associated with GH deficiency are presented in **Table 32-24**.[41,175,176] Children with GH deficiency often present with short stature, plump physique, and a round immature-looking face. When compared with the general population, adults with GH deficiency have increased fat mass, reduced muscle mass and strength, and lower bone density.[176,177]

Table 32-24 Signs and Symptoms Associated with Drug-Induced Growth Hormone Deficiency

Children

- Reduced growth velocity
- Short stature

Adults

- Central obesity
- Decreased lean muscle mass
- Decreased well-being
- Difficulty forming relationships
- Dyslipidemia
- Emotional lability
- Impaired socioeconomic performance
- Increased homeostasis model assessment
- Low bone mineral density

- Reduced energy
- Reduced muscle strength
- Social isolation

The diagnosis of drug-induced GH deficiency is based on signs and symptoms of disease combined with documented low GH under provocative testing (e.g., an insulin tolerance test) and use of an agent known to cause the disease. Low serum GH concentration alone is not conclusive because GH secretion is pulsatile.[178] A diagnosis of GH deficiency can be made if the serum GH concentration in response to insulin-induced hypoglycemia is ≤5 mcg/L or ≤4 mcg/L using the GHRH–arginine stimulation test as measured by radioimmunoassay in adults.[178] In children and adolescents, the diagnosis is made if the serum GH concentration after provocative testing is <10 mcg/L.[175] The standard provocation used to stimulate GH is the insulin-induced hypoglycemia stimulation test, but the GHRH–arginine stimulation test provides a safer alternative in children and in patients with a history of seizure disorder and cardiovascular disease.[178] Alternative causes, such as pituitary adenoma, genetic GH deficiency, abuse/neglect, and diabetes, must still be ruled out (**Table 32-25**).

Table 32-25 Conditions to Consider in the Differential Diagnosis of Drug-Induced Growth Hormone Deficiency

- Brain tumor (craniopharyngioma)
- Central nervous system surgery or radiation
- Cushing syndrome
- Genetic growth hormone deficiency
- Hypothyroidism
- Idiopathic growth hormone deficiency
- Metabolic disturbances (e.g., uncontrolled diabetes)
- Noonan syndrome, Turner syndrome
- Prepubertal
- Short stature associated with abuse or neglect

RISK FACTORS

The main risk factor associated with GH deficiency is the presence of Cushing syndrome, which usually manifests as weight gain and is frequently associated with growth failure. The severity of growth impairment is directly related to the age at onset and the duration of hypercortisolemia.[179] Patients with Cushing syndrome can have persistent impairment of GH secretion long after correction of hypercortisolism. Several factors may play a role in this phenomenon, including delayed remission of hypercortisolism and, in cases of surgically treated Cushing syndrome, damage to the pituitary gland. Sustained hypercortisolism for long periods has also been suggested to impair the physiological function of somatotropes.[171] Therefore, any drug that may induce Cushing syndrome or cause sustained hypercortisolism (e.g., long-term administration of glucocorticoids) should be considered a risk factor (Table 32-19).

MORBIDITY AND MORTALITY

The risk of death from drug-induced GH deficiency is unknown, but data suggest that adults with GH deficiency from other causes have reduced life expectancy.[177] Increased mortality is mostly attributed to premature cardiovascular disease, possibly due to dyslipidemia and insulin resistance, and may be more pronounced in childhood-onset GH deficiency and in females.[180]

PREVENTION

General strategies to prevent drug-induced GH deficiency are presented in **Table 32-26**. In children, the growth velocity should be closely monitored throughout treatment with a known causative agent and timely diagnostic testing should be performed if GH deficiency is suspected. Because Cushing syndrome is a risk factor for GH deficiency, patients presenting with Cushingoid symptoms should be evaluated for evidence of concomitant GH deficiency. When feasible, use of nonsystemic corticosteroids, or corticosteroids with lower potency, may reduce the risk of developing GH deficiency.

Table 32-26 Approaches to Help Prevent Drug-Induced Growth Hormone Deficiency

- Avoid drug–drug interactions that will increase plasma concentrations of the offending agent
- Close monitoring of signs and symptoms during treatment with known causative agent (e.g., growth velocity in children)
- Use alternative route of administration to minimize systemic absorption
- Use lowest effective dose and avoid prolonged use of offending agent

MANAGEMENT

Management of drug-induced GH deficiency is dependent on recognition of the offending drug. Whenever possible, the offending medication should be discontinued in favor of an appropriate therapeutic alternative. In children whose growth has been impaired by persistent hypercortisolism, GH therapy should be initiated as soon as cortisol has normalized because a limited window of opportunity exists to promote increased linear growth. Additionally, GH therapy has been shown to improve body composition in the majority of children.[171] On the other hand, the role of GH replacement in adults has been controversial. GH replacement may be considered for symptomatic relief as well as to increase muscle mass, decrease fat mass, and increase bone mineral density.[32,176,181]

Dosing of recombinant GH is individualized to patient need. In general, premenopausal women and women taking estrogen therapy require higher doses than men because of reduced GH response in the periphery due to estrogen.[178] Children typically require much higher doses than adults. Somatropin should be started at low doses (e.g., 200–300 mcg/day) and slowly titrated upward by 100–200 mcg/day every 1–2 months in adults. Somatropin is routinely started at 20 mcg/kg/week for children.[175,178] Subcutaneous injections may be administered at various intervals (e.g., nightly, every other night, or once per week at night). Clinical response, adverse effects, and the measurement of insulin-like growth factor 1 concentrations guide therapy in adults.[178] In children, height and height velocity are the main therapeutic outcomes, with normalization of growth the goal of therapy.[175] Somatropin may be discontinued in children when growth normalizes and full somatic development (i.e., maximal bone and muscle mass) is achieved.[175] Normalization of GH sensitivity in adults may take up to 2 years.[32] Limited data exist on the benefits of somatropin in drug-induced GH deficiency; however, studies in adults with GH deficiency have shown reductions in cardiovascular disease and risk of fractures.[182,183] Indefinite GH replacement may be considered if the offending agent must be continued. **Table 32-27** summarizes management strategies.

Table 32-27 Management of Drug-Induced Growth Hormone Deficiency

- Discontinue offending agent or initiate appropriate therapeutic alternative
- Children
  - Initiate growth hormone (somatropin) at 20 mcg/kg/wk; height and height velocity guide therapy
  - Goal: growth normalization
- Adults
  - Initiate growth hormone (200–300 mcg/day) for symptomatic relief and to increase muscle mass, decrease fat mass, and increase bone mineral density
  - Titrate dose by 100–200 mcg every 1–2 months; clinical response, adverse effects, and insulin-like growth factor 1 concentrations guide therapy
  - Goal: Normalization of growth hormone sensitivity

INFORMATION FOR PATIENTS

Patients receiving recombinant GH should be informed that slow titration over months is necessary to reduce adverse effects associated with treatment. Common dose-dependent adverse effects include fluid retention, arthralgia, myalgia, headache, nausea, and vomiting. Injection site reactions are also common and dose-dependent. GH requirements change with age and can be affected by sex hormone replacement. Testosterone sensitizes tissues, whereas oral estrogen causes a reduced response to GH. If transdermal estrogen is used to replace oral estrogen, a lower dose of GH may be needed.[178]

HYPOALDOSTERONISM AND HYPERALDOSTERONISM

Hypoaldosteronism is rare and usually not related to medications. Nevertheless, generalized secondary adrenal insufficiency may be responsible for a subset of patients with nonselective hypoaldosteronism.[41] Likewise, most cases of hyperaldosteronism are primary and are often due to physiologic abnormalities that arise in the adrenal cortex.[41,184] A small number of patients may present with secondary hyperaldosteronism that occurs as a result of overstimulation of the zona glomerulosa by the renin–angiotensin–aldosterone system. Excess potassium intake and use of oral contraceptives may also contribute. Signs and symptoms include hypokalemia, hypertension, and possibly evidence of end-organ damage. Correction of the extra-adrenal stimulation of aldosterone secretion usually resolves this disorder. Normalizing serum potassium, considering alternative forms of contraception, and therapy with spironolactone should also be considered.

CHAPTER 33

Sexual Dysfunction in Males

Mary Lee and Roohollah Sharifi

Sexual dysfunction in males can be broadly classified into five major types: disorders of libido (increased or decreased sexual drive), erectile dysfunction (penile impotence), ejaculatory disorders (premature ejaculation, delayed ejaculation, emission failure or anejaculation, decreased ejaculation volume, or retrograde ejaculation), priapism (prolonged, painful erection), and infertility. Although some patients suffer from only one type of sexual dysfunction, others may experience more than one. In some cases, a patient may suffer from one disorder, and then secondarily another type of sexual dysfunction develops. For example, an elderly menopausal male patient may experience decreased libido, and then erectile dysfunction develops secondary to the lack of sexual drive. Some drugs have the potential to cause several types of sexual dysfunction. For example, phenothiazine antipsychotic agents may cause decreased libido, erectile dysfunction, or priapism, which may occur together in some patients or separately in others.

CAUSATIVE AGENTS

Table 33-1, **Table 33-2**, **Table 33-3**, **Table 33-4**, and **Table 33-5** list the many drugs that have been commonly reported to cause various types of sexual dysfunction in males. Many of the published references used to create these tables are observational studies, case reports, or case series. Thus, a cause-effect relationship has not been established for many of the drugs. An effort was made to include drugs for which a proposed mechanism for the drug-induced disease could be described based on the drug's pharmacologic effects. Thus, Tables 33-1 to 33-5 should not be considered exhaustive lists.

Key to the interpretation of the published literature on drug-induced sexual dysfunction is the fact that, in some cases, the disease for which the offending drug was prescribed is, itself, a risk factor for sexual dysfunction. For example, diuretics are a common cause of erectile dysfunction. However, diuretics are commonly prescribed for hypertension, which itself may cause erectile dysfunction. Also, sexual dysfunction is generally an underreported adverse effect. Many patients are uncomfortable sharing information about this and some healthcare providers do not routinely question patients about this adverse drug reaction.

Table 33-1 Agents Implicated in Drug-Induced Decrease in Libido

Drug	Incidence	Level of Evidence
5α-reductase inhibitors[1-3]	6.4%, up to 94%[1]	A,B
Anabolic steroids[4]	25%	A,B
Antidepressants, tricyclic[5]	NK[a]	C
Antidepressants, selective serotonin reuptake inhibitors[6]	1–12%	A
Antidepressants, other[5]	4%	A
Atypical antipsychotics[7,8]	0.1–5%, up to 60%	A
β-adrenergic antagonists[9]	NK	C
Carbamazepine[10]	22–67%	B
Cimetidine[11,12]	1–4%[b]	C
Cocaine[13]	NK	C
Digoxin[14]	NK	C
Estrogens[15]	8%	B
Ethanol[16]	NK[c]	C
Gonadotropin-releasing hormone agonists[15]	NK[d]	A

Gonadotropin-releasing hormone antagonists[17]	NK	C
Haloperidol[15]	NK	C
HMG CoA reductase inhibitors[18,19]	NK	C
Hypnotics, benzodiazepines[15]	NK	C
Isotretinoin[20]	NK	C
Ketoconazole[16,21]	NK	B
Levetiracetam[22]	NK	C
Lithium[23]	NK	C
Metoclopramide[15]	NK	C
Opiates (natural and synthetic)[24-28]	19%[e]	B,C
Phenothiazines[29]	NK[f]	B
Proton pump inhibitors[30]	NK	C
Spironolactone[13]	NK[g]	B

NK = not known.

[a] Most common with tertiary amines, as these have the highest incidence of sedative adverse effects.

[b] Uncommon. Most often reported with high-dose parenteral drug treatment.

[c] Common with high doses of ethanol. Low doses may improve libido.

[d] Common after the first 2–3 wk of the start of treatment. This adverse effect is likely underreported because patients who receive this medication may not be sexually active.

[e] Associated with morphine doses of 100 mg orally/day or its equivalent.

[f] Common with highly sedating phenothiazines. Less common with less-sedating agents: thiothixene, haloperidol, or loxapine.

[g] Common in patients treated with large daily doses (e.g., those with hyperaldosteronism).

Table 33-2 Agents Implicated in Drug-Induced Erectile Dysfunction

Drug	Incidence	Level of Evidence
α-adrenergic antagonists[2]	0–2.8%	A
5α-reductase inhibitors[1,2,32-36]	8.1–18.5%	A
Amiodarone[9,37]	NK	C
Antiandrogen (e.g., flutamide, ketoconazole)[37]	NK	C
Antihistamines[13]	NK[a]	C
Antiparkinsonian agents[13]	NK	C

Antidepressants, norepinephrine and serotonin reuptake inhibitors[38]	1–5%	A
Antidepressants, selective serotonin reuptake inhibitors[38,39]	0–13%[b]	B, C
Antidepressants, tetracyclic[29]	0.1–1%	A
Antidepressants, tricyclic[13]	NK	B
Antidepressants, other[38]	3.4%[b]	A
Antipsychotics, first generation (e.g., chlorpromazine, thioridazine, etc.)[6,8]	NK[c]	C
Antipsychotics, atypical[23]	0.1–1%[d]	A
β-adrenergic antagonists[9,31,41,42]	6–40%[e,f]	C
Baclofen[43,44]	0.2–1.6%	A
Benzodiazepines[45,60]	NK	C
Busulfan[37]	NK	C
Calcium-channel antagonists[41,46]	<1%	A
Celecoxib[47]	NK	C
Cocaine[37]	NK	C
Central α-adrenergic agonists[48]	3–7%, up to 24%	A
Cyclophosphamide[37]	NK	C
Digoxin[37]	NK	C
Disopyramide[13-15]	1–3%	A
Diuretics, thiazides[13-15,31,42,48]	10–20%[f]	B
Diuretics, loop[13-15,42,48]	NK[f]	C
Estrogens[15]	12%	A
Ethanol[37]	NK	C
Gabapentin[49-51]	1.5%	A
Gemfibrozil[13,52]	NK	C
Gonadotropin-releasing hormone agonists[53]	4%[g]	A
Gonadotropin-releasing hormone antagonists[17]	NK[g]	C
Guanethidine[48]	54%	B
Haloperidol[33,40]	NK	C
Histamine H_2-receptor antagonists (e.g., cimetidine)[45]	NK	C

HMG-CoA reductase inhibitors[52,54-58]	Variable	B,C
Lithium carbonate[15,40,59,60]	NK	C
Marijuana[37,61]	Variable	C
Methyldopa[48]	36%[f,h]	B
Monoamine oxidase inhibitors[13,40]	NK	C
Nonsteroidal anti-inflammatory agents[45,47,62,63]	9.7%	B
Omeprazole[64-66]	NK	C
Opiates[67]	Up to 50%[h]	B
Phenothiazines[6,13-15]	N[c,h]	B
Pregabalin[68]	71%	A
Protease inhibitors[69]	6%	B

Spironolactone[13-15]	4–30%[h]	C
Topiramate[70-72]	≥1%	A

NK = not known.

[a] Frequency is highest with drugs with the greatest anticholinergic or sedative adverse effects.

[b] Frequency is lower with antidepressants with lower anticholinergic adverse effects and lower serotoninergic effects (e.g., bupropion, nefazodone, vilazodone, mirtazapine).[40,79,157,175]

[c] Frequency is highest with thioridazine, which has the greatest anticholinergic potency as compared with other agents. Some literature suggests using prolactin-sparing agents (e.g., aripiprazole, clozapine, olanzapine, quetiapine, and ziprasidone), but this has variable results.[6]

[d] Of these agents, risperidone has been reported to cause the highest incidence (>5%).

[e] Frequency is highest with lipophilic drugs, which cross the blood–brain barrier.

[f] Antihypertensives with a lower prevalence of erectile dysfunction include angiotensin-converting enzyme inhibitors, angiotensin II antagonists, and calcium-channel antagonists.

[g] Because these medications lower serum testosterone to castration levels, the incidence is probably much higher. However, patients receiving this medication may not report this adverse effect because they are not sexually active.

[h] Frequency is dose-related.

Table 33-3 Agents Implicated in Drug-Induced Ejaculation Disorders

Drug	Incidence	Level of Evidence
α-adrenergic antagonists[73,74,76,77]	9.7–28.1%[a,b]	A,B
5α-reductase inhibitors[1,2,32-35,76]	0.1–7.2%[c]	A

Antidepressants, selective serotonin reuptake inhibitors[29,40,78-83]	6–28%[d]	A
Antidepressants, tricyclic[79,81,82]	NK	C
Antidepressants, tetracyclic[82,84]	<0.1%	A
Antidepressants, norepinephrine and serotonin reuptake inhibitors[82,85]	2–3%	A
Antidepressants, triazolopyridine[82,86]	NK	C
Antidepressants, other[87]	0.1–1%	C
Antipsychotics, atypical[6,88-91]	0–5%	A
Baclofen[92]	NK	A
Haloperidol[6,91]	NK	C
Monoamine oxidase inhibitors[6,38,82]	NK	C
Naproxen[91]	NK	C
Phenothiazines[78]	NK	C
Thiazide diuretics[42]	NK[e]	C
Topiramate[90,92]	1–3%	C

NK = not known.

[a] Highest incidences reported with tamsulosin 0.8 mg per day and silodosin (90%).[2,7,75,76]

[b] Combination of α-adrenergic antagonist and 5α-reductase inhibitor is associated with threefold increase in ejaculation disorders compared to either drug alone.[76]

[c] Variable incidence rates reported. Rates as high as 20% reported.[33]

[d] Occurs in up to 50% of patients treated with paroxetine. Paroxetine is associated with the highest incidence as compared with other agents in this class.

[e] Incidence of ejaculation disorders is much lower than those of erectile dysfunction and decreased libido.

Table 33-4 Agents Implicated in Drug-Induced Priapism

Drug	**Incidence**	**Level of Evidence**
Adalimumab[93]	NK	C
α-adrenergic antagonists[94-96]	<1%	A
Alprostadil[97,98]	0.4%[a]	A
Antianxiety agents	NK	C
Antidepressants[29,40]	NK	C
Antidepressants, selective serotonin reuptake inhibitors[40,99-102]	NK	C
Antidepressants, triazolopyridine (e.g.,	NK	C

trazodone)[38,40,103,104]		
Antipsychotics, atypical[6,105-113]	0.1–1%	A
Atomoxetine[114]	NK	C
Buspirone[115]	NK	C
Cocaine[116]	NK	C
Ethanol[115]	NK	C
Fat emulsion, intravenous[117]	NK	C
Heparin[118-120]	NK	C

Sodium valproate[134]	NK	C
Warfarin[118,120,135]	NK	C

NK = not known.

[a] Usually occurs when administered intracavernosally or intraurethrally in large doses, or when used along with other erectogenic drugs.

[b] Usually occurs when administered in large doses intracavernosally or when used along with other erectogenic drugs.

[c] This drug category is one of the most common causes of priapism in clinical practice.

[d] Usually when used in excessive doses or when combined with other erectogenic agents.

EPIDEMIOLOGY

Up to 25% of cases of erectile dysfunction may be drug induced, and the most common offending agents are thiazide diuretics, β-blockers, antipsychotic agents, and antidepressants. According to the Massachusetts Male Aging Study, which was conducted in male outpatients aged 40 to 70 years, up to 51% of men had some degree of erectile dysfunction.[16,149] Erectile dysfunction was more common in men who were taking antihypertensive drugs, oral hypoglycemic agents, vasodilators, or cardiac medications. In the 4-year Treatment of Mild Hypertension Study, patients responded to an annual survey of sexual function. At the 2-year point, the incidence of the inability to achieve an erection was 2.8%, 15.7%, and 4.9% in the doxazosin, chlorthalidone, and placebo groups, respectively.[31] In contrast, the incidences of drug-induced disorders of libido, ejaculation, priapism, or fertility are not as well studied, and therefore, less data are available.

Table 33-5 Agents Implicated in Drug-Induced Infertility

Drug	Incidence	Level of Evidence
Anabolic steroids[4,136]	NK[a]	C
Antidepressants, selective serotonin reuptake inhibitors[137,138]	NK[b]	B
Antineoplastic agents, alkylating[23,139,140]	Up to 100%[a,c]	B
Carbamazepine[141]	NK	C
Cimetidine[23,118]	NK	C
Cisplatin[139,140]	Up to 100%[d]	B
Corticosteroids	100%[e]	B
Erythromycin[142]	NK	C
Escitalopram[143]	NK[b]	C
Estrogens[23]	NK[f]	C
Ethanol, chronic use[144]	NK[f]	C
Gonadotropin-releasing hormone agonists[145]	NK[f]	B
Ketoconazole[146]	NK[a,g]	C
Nitrofurantoin[146,147]	NK[a,g]	C
Phenothiazines[23]	NK	C
Spironolactone[23]	NK[a]	C
Sulfasalazine[118]	NK	C
Testosterone undecanoate[148]	NK[h]	C

NK = not known.

[a] Frequency is dose-related.

[b] Has been shown to decrease sperm concentration and motility or to increase the concentration of sperm with abnormal morphology.[137,138]

[c] Incidence increases with dose and duration of treatment, and if chemotherapy is administered with radiation therapy or in combination with other chemotherapy known to affect spermatogenesis.

[d] Up to 100% of patients become infertile when cisplatin is used to treat testicular cancer. When dose is 0.6 g/m2 or higher, azoospermia develops in most patients.

[e] This applies to patients treated with corticosteroids in pharmacologic doses in combination with antineoplastic chemotherapy regimens.

[f] Probably common; however, incidence not studied.

[g] Not reported with usual therapeutic doses; occurs with large doses.

[h] This is based on high-dose testosterone supplementation for an infertile couple.

A wide range of prevalence rates has been reported for sexual dysfunction associated with specific drugs. This is related to methodological limitations in study design, including the absence of validated sexual dysfunction survey tools used at baseline and during the trial to assess the presence of disorders, and the lack of objective assessments to confirm a patient’s self-reported complaints.[40] In addition, patient factors directly influence the frequency of reported sexual dysfunction, including the willingness of the patient to report the adverse effect, persistence of the healthcare provider in questioning the patient about the adverse effect, patient’s age and general health status, whether or not the patient is a smoker or uses recreational drugs, dosage regimen of the offending agent, use of the offending agent in combination with other drugs that could also cause sexual dysfunction, and concurrent medical illnesses that could contribute to sexual dysfunction.[150,151]

MECHANISMS

Mechanisms of drug-induced sexual dysfunction are dependent on the type of dysfunction (**Table 33-6**). A normal male libido is mediated by serum androgen concentrations. Testosterone is the chief male androgen, comprising 90% of circulating androgens, and is produced by the testes. Serum testosterone concentrations are responsible for male sexual drive.[150,164] The role of dihydrotestosterone, the chief active metabolite of testosterone, in maintaining libido is not clear. In patients with primary hypogonadism who have serum testosterone concentrations that are below the normal range, exogenous administration of testosterone replacement agents restores libido.[165]

Table 33-6 Mechanisms of Drug-Induced Sexual Dysfunction in Males

Drug	**Mechanism**
DRUG-INDUCED DECREASED LIBIDO	
5-α reductase inhibitors	Decrease dihydrotestosterone in the central nervous system[1,34,35]
Anabolic steroids	Suppress hypothalamic–pituitary–gonadal axis[4]
Antidepressants	Cause sedation, which depresses libido[5,40]
Antipsychotics	Cause sedation, which depresses libido[6,7]
β-adrenergic antagonists	Cause sedation, particularly the lipophilic agents (e.g., propranolol)[152]
Carbamazepine	Increases sex hormone–binding globulin, which decreases serum free (active) testosterone levels[153,154]
Cimetidine	Increases prolactin, which depresses androgen production; may be an androgen receptor antagonist[11-15]
Clofibrate	Reduces cholesterol, a precursor for androgen synthesis[9,13-16]
Digoxin	(Metabolite) Competes with androgen at receptors[13-16]
Estrogens	Decrease pituitary LH secretion and testicular testosterone production
Ethanol, high doses	Causes sedation, which depresses libido[13-16]
Gemfibrozil	Reduces cholesterol, a precursor for androgen synthesis[13-16]
Gonadotropin-releasing hormone agonists	Decrease pituitary LH secretion and testicular testosterone production[50]
Gonadotropin-releasing hormone antagonists	Decrease pituitary LH secretion and testicular testosterone production[155]
HMG-CoA inhibitors	Decrease serum testosterone[17,18,19,52]
Hypnotics	Cause sedation, which depresses libido[13-15]
Ketoconazole	Inhibits adrenal and testicular testosterone production[21]
Methadone	Increases serum prolactin, which depresses androgen production[156]
Metoclopramide	Increases prolactin, which depresses androgen production[13-15]

Opiates	Suppress hypothalamic–pituitary–gonadal axis and decrease pulsatile release of luteinizing hormone[24-27,67]
Phenobarbital	Increases sex hormone–binding globulin, which decreases serum free (active) testosterone levels[153,154]
Phenothiazines	Increase prolactin, which depresses androgen production; has sedative effects[6-8]
Phenytoin	Increases sex hormone–binding globulin, which decreases serum free (active) testosterone levels[46,153,154]
Spironolactone	Competes with androgen at receptor (metabolite) Inhibits testosterone synthesis[13,14]
DRUG-INDUCED ERECTILE DYSFUNCTION	
5-α reductase inhibitors	Decrease dihydrotestosterone, which may result in decreased smooth muscle in cavernosal tissue and apoptosis of cells[1,2,36,159]
Anticonvulsants	Sedative adverse effects decrease libido; patients may develop erectile dysfunction secondary to decreased libido.[15,16] Some agents with potent hepatic microsomal enzyme-inducing properties (e.g., phenytoin, carbamazepine) may increase sex hormone–binding globulin, thereby decreasing free (active) testosterone.[153,154]
Antidepressants	Sedative adverse effects decrease libido; patients may develop erectile dysfunction secondary to decreased libido; anticholinergic effects decrease arterial blood flow into and filling of corpora cavernosa.[5] Also, antidepressants with strong serotoninergic properties (e.g., fluoxetine, paroxetine, citalopram, or sertraline) are associated with the higher prevalence of sexual dysfunction than agents that have less potent serotoninergic effects (e.g., bupropion, mirtazapine, nefazodone, vilazodone).[40,157,158] Selective serotonin reuptake inhibitors activate central serotonin receptors, which inhibit neurotransmission of norepinephrine and dopamine.[40]
Antihistamine	Sedative adverse effects cause decreased libido; patients develop erectile dysfunction secondary to decreased libido.
Anticholinergic-antiparkinsonian agents (e.g., benztropine)	Anticholinergic effects decrease arterial blood flow into and filling of corpora cavernosa.[13-15]
Antipsychotics (phenothiazines, atypical antipsychotics)	

	Sedative adverse effects cause decreased libido; patients develop erectile dysfunction secondary to decreased libido. Anticholinergic effects decrease arterial blood flow into and filling of corpora cavernosa; in addition, some antipsychotic agents antagonize dopamine, which results in increased prolactin[167]; increased prolactin is also associated with decreased testicular testosterone production.[6,160]
β-adrenergic antagonists	Decrease systemic blood pressure resulting in decreased blood flow to corpora cavernosa, may decrease libido and cause erectile dysfunction secondarily, decrease central sympathetic outflow Prevalence may be greater with lipophilic agents.[13-15]
Digoxin	Blocks smooth muscle relaxation of corpora cavernosa, which inhibits blood filling[9]
Diuretics, thiazide or loop Centrally acting sympatholytics (e.g., clonidine)	Decrease systemic blood pressure resulting in decreased blood flow to corpora cavernosa[13-15,42]
Estrogens Gonadotropin-releasing hormone agonists Gonadotropin-releasing hormone antagonists	Decreased serum testosterone concentrations causing decreased libido and secondary erectile dysfunction[50,53,155]
Ethanol, high doses Hypnotics	Sedative adverse effects cause decreased libido; patients develop erectile dysfunction secondary to decreased libido.[13-15]
Haloperidol	Blocks D_1 and D_2 receptors in the central nervous system[6]
Pregabalin	Decreases release of neurotransmitters (e.g., glutamate, substance P, and calcitonin gene-related peptide)[161]
Topiramate	Interferes with blood flow to corpora cavernosa[70]
DRUG-INDUCED EJACULATION DISORDERS	
α-adrenergic antagonists	Relaxation of bladder neck during coitus leads to retrograde or delayed emission.[6,73,76,77,87-89,162]
Antipsychotics, atypical Phenothiazines	Inhibit α-adrenergic receptors at the bladder neck, leading to retrograde or delayed ejaculation[7,90]
5α-reductase inhibitors	Decrease in prostate volume leads to decrease in ability of prostate to produce prostatic secretions; decreased semen volume results.[163]
Anticholinergic agents Phenothiazines[40,80] Tricyclic antidepressants[38,80]	Anticholinergic effects lead to delayed emission.[78,80]

Guanethidine	Blocks contraction of vas deferens, which results in delayed emission[48]
Antidepressants, selective serotonin reuptake inhibitors[29,40,78-83]	Stimulate central 5-HT$_2$ receptors, which leads to emission failure
Trazodone	Stimulate central serotonin receptors and causes peripheral α-adrenergic blockade, which leads to an ejaculation[82,86]
DRUG-INDUCED PRIAPISM	
Fat emulsion, intravenous Heparin[119] Warfarin[18]	Cause a hypercoagulable state[117]
Aripiprazole[107] Phenothiazines[6,128] Clozapine[108] Quetiapine[110,132] Risperidone[105,112,113]	α-adrenergic blockade prevents detumescence of the penis.
Bupropion[40]	α-adrenergic blockade prevents detumescence of the penis.
Antidepressants, selective serotonin reuptake inhibitors[40]	Central serotonin stimulation may also lead to low-flow priapism.
Trazodone[103,104]	α-adrenergic blockade prevents detumescence of the penis.
Hydralazine α-adrenergic antagonists[94-96]	Arteriolar vasodilation increases blood flow to corpora cavernosa.[9,97]
Alprostadil[97,98] Papaverine[126,127]	Increase cyclic AMP in cavernosal tissue, which increases blood filling of sinusoidal tissue
Phosphodiesterase type 5 inhibitors (e.g., sildenafil, vardenafil, tadalafil, avanafil)	When used in excessive doses or when combined with other erectogenic drugs, they increase cyclic GMP in cavernosal tissue, which increases blood filling of sinusoidal tissue.[130,131]
DRUG-INDUCED INFERTILITY	
Anabolic steroids	Suppress hypothalamic–pituitary gonadal axis[4]
Antineoplastic agents	Damage germinal epithelium in testes; sperm production is impaired.[23,139,140]
Estrogens Gonadotropin-releasing hormone superagonists Ketoconazole Spironolactone	Decrease serum testosterone concentration or block testosterone at receptors, which interfere with maturation of spermatogonia[23,145,146]
Cimetidine	Blocks androgen receptor, which interferes with maturation of spermatogonia[23,118]

Erythromycin	Decreases sperm motility and sperm number[142]
Ethanol, chronic	Decreases testosterone production, which interferes with sperm maturation[144]
Nitrofurantoin	Inhibits sperm maturation and protein synthesis, which interferes with sperm motility[147]
Sulfasalazine	Decreases sperm production, maturation, and motility[118]
Testosterone undecanoate	Suppresses FSH and LH, which decreases sperm production and maturation[148]

AMP = adenosine monophosphate, FSH = follicle-stimulating hormone, GMP = guanosine monophosphate, HT = hydroxytryptamine, LH = luteinizing hormone.

The hypothalamic–pituitary–gonadal–adrenal axis controls testicular testosterone production. Increased release of luteinizing hormone-releasing hormone or gonadotropin-releasing hormone from the hypothalamus stimulates pituitary release of luteinizing hormone. Luteinizing hormone stimulates the production of testosterone in Leydig cells. Therefore, drugs that suppress hypothalamic release of luteinizing hormone-releasing hormone or pituitary release of luteinizing hormone, or that directly suppress testicular testosterone production,[166] may suppress libido. Similarly, drugs that increase serum prolactin concentrations, which results in a decrease in testicular androgen production, can indirectly suppress libido.[167] In addition to the stimulatory effect of testosterone on libido, males must be conscious and receptive to sexual stimuli, which can be visual, auditory, olfactory, tactile, or gustatory. As these stimuli are processed in the brain, drugs that cause sedation or depress the sensorium can suppress libido.[166]

Theoretically, it follows then that supraphysiologic serum testosterone concentrations may enhance male sexual drive in elderly patients. However, this has not been demonstrated clinically. Administration of excessive doses of testosterone to elderly male patients, resulting in supraphysiologic serum testosterone concentrations, is not associated with increased libido.[165,168] The mechanism for increased sexual drive is poorly understood and may be due to a combination of causes, including a supratentorial component.

In order for a penile erection to occur, a patient must have intact penile vascular and neurologic systems. The penis is composed of three vascular bodies: two dorsal corpora cavernosa and one corpus spongiosum. During an erection, the corpora fill with arterial blood, which must be trapped within the corpora. Thus, arterial blood flow must be adequate and the degree of arterial inflow must exceed the degree of venous outflow for penile tumescence to occur. When compounded by contraction of the ischiocavernosus muscles surrounding the bulbous urethra, these effects produce a long, hard, penile shaft suitable for vaginal penetration. Thus, systemic antihypertensive agents, which decrease peripheral blood pressure, or diuretics, which decrease blood volume, may compromise arterial blood flow and cause erectile dysfunction.[169]

Both the central and peripheral nervous systems can mediate a penile erection. With visual, olfactory, auditory, tactile, or gustatory sexual stimulation, the brain sends nerve impulses down the spinal cord. Preganglionic sympathetic nerve fibers emerge from the spinal cord at the thoracolumbar vertebra T11-L2; postganglionic neurotransmission to the corpora is mediated by parasympathetic pathways in the pelvic plexus. Tactile stimulation of the genitalia can also stimulate a somatic reflex nerve arc at the level of the sacral vertebrae S2 to S4. In either case, acetylcholine is the primary neurotransmitter responsible for penile tumescence. Acetylcholine probably works through noncholinergic, nonadrenergic neurotransmitters, such as nitric oxide, and secondary messengers, such as cyclic adenosine monophosphate and cyclic guanine monophosphate, to mediate corporal relaxation and blood filling of cavernosal tissue sinuses. Therefore, drugs that antagonize acetylcholine at its receptor, producing anticholinergic effects, can cause erectile dysfunction.[169]

In male patients with normal sexual function, antegrade ejaculation of seminal fluids out of the urethra occurs at climax. Antegrade ejaculation requires emission (or the movement of seminal fluids from the prostate, seminal vesicles, and vas deferens into the proximal urethra); contraction of the bladder neck sphincter (to prevent the retrograde flow of seminal fluids into the bladder); and contraction of periurethral skeletal muscles to propel the ejaculate out of the urethra. Emission and bladder neck closure are sympathetically mediated by norepinephrine.[170] Thus, postsynaptic α-adrenergic receptor antagonists (e.g., tamsulosin) block norepinephrine at its receptor and may lead to retrograde ejaculation or emission failure.[170] The antegrade propulsion of ejaculate from the posterior urethra and out of the patient’s body is parasympathetically mediated. Thus, drugs with anticholinergic effects may cause delayed ejaculation.[40,78,80,91] In addition, stimulation of central serotonin receptors appears to inhibit ejaculation. Thus, selective serotonin reuptake inhibitors are associated with anejaculation.[171]

The ejaculate is composed of three major components: sperm-containing fluid from the vas deferens, fructose-containing fluid from the seminal vesicles, and prostatic secretions from the prostate. A normal ejaculate volume is 2 to 6 mL. Contributors of ejaculate volume include the seminal vesicles (75–80% of the total volume) and prostate (10% of the total volume), both of which are androgen-dependent tissues. Thus, medications that interfere with testosterone stimulation of these target tissues (e.g., finasteride) can decrease ejaculate volume.[78]

Following climax and ejaculation, the penis returns to a flaccid state. For detumescence to occur, venous outflow must exceed arterial inflow. Detumescence is sympathetically mediated. Therefore, norepinephrine normally causes arteriolar vasoconstriction, thereby decreasing arteriolar inflow and causing cavernosal vasoconstriction. This improves venous outflow, and the penis eventually becomes flaccid. β_2-adrenergic stimulation of peripheral blood vessels causes venodilation, which improves venous outflow and blood emptying from the corpora cavernosa. When detumescence does not occur, and the penile erection is sustained in the absence of sexual stimulation, priapism can develop. Penile pain may result from blood sludging within and hypoxia of cavernosal tissue. Permanent cavernosal injury may develop if priapism does not resolve on its own or is not treated appropriately.

The mechanism of drug-induced priapism is poorly understood. Priapism may result from drug-induced increased arteriolar inflow to the cavernosa (e.g., hydralazine), drug-induced decreased venous outflow mediated by inhibition of α-adrenergic tone (e.g., phentolamine, phenothiazines, trazodone), blood sludging in the corpora because of platelet or clotting factor dysfunction (e.g., heparin, warfarin), or some other mechanism.[172]

The fertility of a male is dependent on multiple physiologic functions: adequate quantitative and qualitative production of sperm and effective emission of sperm into the prostatic urethra. Luteinizing hormone and follicle-stimulating hormone (FSH) are essential for the induction of sperm production at puberty. After puberty, maintenance of spermatogenesis is dependent on FSH stimulation of Sertoli cells and the presence of adequate concentrations of testosterone in the seminiferous tubules so that spermatogonia can undergo differentiation and maturation into spermatozoa.[173] Normal semen parameters include a semen volume of 2 to 6 mL, a sperm concentration of at least 20 million per mL, at least 50% to 60% motile sperm, and at least 30% of sperm with normal morphology.[173] Although variably defined, infertility refers to the inability of the female partner to become pregnant after 1 year or more of purposeful attempts to conceive.[173,174] Infertility can be due to an inadequate number of sperm in the semen; abnormal sperm morphology, which interferes with their motility; or their ability to penetrate an egg. Thus, drug-induced infertility can result from damage to the Sertoli cells (e.g., antineoplastic alkylating agents, radiation therapy), interference with the maturation of sperm (e.g., antiandrogens), or motility of sperm (e.g., sulfasalazine, vaginal spermicides).[23] The extent of damage to the germinal epithelium by antineoplastic agents is dependent on the pharmacologic class of agent used (alkylating agents are the most potent, followed by antimetabolites, vinca alkaloids, procarbazine, and cisplatin), dose used (higher doses cause worse damage than lower doses), combined use of alkylating agents (combination therapy causes worse damage than monotherapy), age of the patient (prepubertal males tend to be more resistant to the effects of antineoplastic chemotherapy than adult patients), and combined use with radiation (worse than with chemotherapy alone).[140]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Symptoms of drug-induced sexual dysfunction in males are similar to those of patients with sexual dysfunction due to other causes (**Table 33-7**). With decreased libido, patients may report no desire for or interest in sexual intercourse. Patients commonly profess to be busy with work, engaged in other activities, or to not feel well and use these as excuses for having no desire. Decreased libido often results from a recent history of divorce, separation from a loved one, death of a spouse, sudden job loss, or performance anxiety. Patients with increased libido usually do not come to the attention of a clinician unless the patient's sexual desires are inappropriate, such as in precocious puberty.[165]

Table 33-7 Signs and Symptoms Associated with Drug-Induced Sexual Dysfunction in Males

Decreased libido

- Decreased or absent desire for sexual intercourse, depressed mood
- Gynecomastia, small testicles, decreased muscle mass, and decreased axillary and pubic body hair, decreased spontaneous erections, hot flashes, low bone mineral density, and subphysiologic serum testosterone concentrations
- Patient may not complain of this adverse effect if he is not sexually active.
- Symptoms are temporally related to start of causative drug, although onset may be variable after the causative medication is started.
- Usually adverse effect resolves after the causative medication is discontinued.

Erectile dysfunction

- Absence of penile curvature or palpable plaques
- Erectile dysfunction is temporally related to start of causative drug, although onset may be variable after the causative medication is started.
- Erectile dysfunction may persist even after discontinuation of the suspected causative medication.
- Inability to achieve a penile erection sufficient for successful intercourse; partner may express dissatisfaction or frustration with patient.
- Inability to achieve a penile erection with stimulation; patient may have a medical illness that also causes erectile dysfunction for which the causative drug is being taken; for example, the patient may suffer from depression and need to take an antidepressant.
- No signs of infection
- Patient may not complain of this adverse effect if he is not sexually active.
- Usually adverse effect resolves after the causative medication is discontinued.

Ejaculation disorder

- Absent, decreased, or delayed ejaculation; patient reports dry sex or lack of sexual satisfaction/enjoyment during climax; if retrograde ejaculation, patient reports cloudy urine immediately after intercourse; if premature ejaculation, patient reports ejaculation before intercourse or before climax is reached; partner may express dissatisfaction or frustration with patient.
- Ejaculation disorder may persist even after discontinuation of the suspected causative medication.

- Ejaculation disorders are temporally related to start of causative drug, although onset may be variable after the causative medication is started.
- If decreased ejaculation, semen volume is <1.5–2 mL.
- If retrograde ejaculation, microscopic examination of urine after intercourse shows sperm.
- Patient may not complain of this adverse effect if he is not sexually active.

Priapism

- Physical exam shows a rigid, hard dorsal surface of penis and a soft ventral surface.
- Priapism is temporally related to start of the causative drug, although onset may be variable after the causative medication is started.
- Priapism may result in permanent erectile dysfunction if not treated promptly.
- Prolonged erection (>4 hr) in the absence of sexual stimulation; penis is painful and may be bluish in color.
- This is considered a urologic urgency/emergency; patient needs to seek medical attention for this.

Infertility

- Female partner is unable to conceive despite 1 yr of trying.
- Infertility due to radiation therapy and antineoplastic chemotherapy may take 1–10 yr to recover after the causative agent is discontinued; in some patients, drug-induced infertility is irreversible.
- Infertility is temporally related to start of the causative drug, although onset may be variable after the causative medication is started; with antineoplastic chemotherapy, the onset of infertility is commonly 8–12 wk after the start of treatment.
- Semen analysis shows an abnormality: if volume is <1.5–2 mL, <50–60% of sperm are motile; if sperm concentration is <20 million/mL, <30% of sperm have normal morphology; increased serum concentrations of follicle-stimulating hormone.

Patients with erectile dysfunction present with failure to achieve a penile erection sufficient for vaginal penetration. Although periodic erectile dysfunction is generally acceptable, a patient who experiences erectile dysfunction in more than 50% of attempts at sexual intercourse should seek medical treatment if he wishes to be sexually active.[16,37,175]

Patients with ejaculatory dysfunction may present with a variety of symptoms, including premature ejaculation, reduced ejaculation volume, retrograde ejaculation, delayed ejaculation, anejaculation (no ejaculation), or emission failure. With premature ejaculation, the patient ejaculates within one minute of vaginal penetration or before climax is reached, often rapidly followed by detumescence.[171] A chief problem is spousal dissatisfaction with the patient’s sexual performance. Alternatively, some patients report reduced ejaculatory volume. Confirmation of the existence of the problem requires measurement of ejaculatory volume prior to and after the supposed disorder developed, which is rarely performed in clinical practice. Thus, this is more often a subjective report by the patient. On the other hand, in patients with retrograde ejaculation, the patient usually reports “dry sex” and no antegrade flow of seminal fluid during climax. Instead, during the first urine voiding after intercourse, the patient may produce cloudy urine, which indicates the presence of seminal fluid in the urine. The presence of sperm in the urine can be confirmed by microscopic examination of a postejaculation urine sample. Anejaculation is a failure to ejaculate, which may be due to a disorder of emission or a delay in emission. The patient complains of "dry sex."[91]

Patients with priapism often have a sickle cell anemia or chronic granulocytic leukemia, use combinations or large doses of erectogenic drugs, or have a history of unusually prolonged sexual activity or drug abuse. Because of a persistent painful erection for several hours, the patient will present for urgent or emergency care. Priapism more commonly involves the corpora cavernosa as opposed to the corpus spongiosum. Thus, the dorsal surface of the penis will be hard, but not the ventral surface.[172]

In a patient with infertility, the failure to successfully impregnate his female partner after 1 year's time is obvious. However, the diagnostic assessment to determine the cause generally requires an extensive workup, as the cause could be multifactorial.

In the diagnostic evaluation of patients with sexual dysfunction, it is important to take a careful history of present illnesses, past medical problems and surgical procedures, and concurrent medications. In many cases, information should also be obtained from the spouse or significant other so that sensitive data collected from the patient regarding the nature of the sexual dysfunction can be corroborated. Knowledge of past medical problems and concurrent prescription and nonprescription medications is key to rule out diseases or other drugs or drug combinations that could be contributing to the patient's current symptoms.[29] Conditions to consider in the differential diagnosis of drug-induced sexual dysfunction are listed in **Table 33-8**. These medical conditions may cause sexual dysfunction or contribute to drug-induced sexual dysfunction. Therefore, if the latter is suspected, treatment of the underlying medical condition may correct the patient's sexual dysfunction. In addition, patients with erectile dysfunction should be asked to complete a standardized, validated, self-assessment survey of sexual function, such as the International Index of Erectile Function or Brief Sexual Function Inventory.[176] This should be done at baseline and after a corrective measure has been instituted. Physical examination should include gross examination of the external genitalia and assessment of pelvic nerve function, including assessment of genitoperineal pain sensation, the bulbocavernosal reflex, and anal sphincter tone.[151]

Patients evaluated for drug-induced diminished libido should undergo two serial measurements of serum testosterone concentrations, obtained in the morning at the same time each day. Repeated morning measurements are recommended because of the circadian pattern of endogenous testosterone secretion and because of substantial variability in serum testosterone concentrations throughout the day. In addition, the patient should be checked for physical signs of hypogonadism, including gynecomastia, decreased muscle mass, and undersized testes.

In patients with erectile dysfunction, no specific diagnostic tests are usually performed. With the availability of phosphodiesterase inhibitors (e.g., sildenafil), which are effective in the majority of patients with erectile dysfunction independent of the cause, diagnostic testing is not necessary. Nocturnal penile tumescence testing, penile Doppler ultrasound, cavernosography, and cavernosometry are generally reserved for patients with no response to phosphodiesterase inhibitors or when specific surgically correctable organic causes of sexual dysfunction are suspected.

Patients with ejaculatory dysfunction should be requested to provide two semen samples under controlled conditions in the clinic. Each sample should be collected on a different day, and sample collection should be preceded by 3 days of sexual abstinence. The specimen should be checked for ejaculate volume and sperm motility and morphology. If retrograde ejaculation is suspected, a postejaculation urine specimen should also be evaluated for the presence of sperm.

Table 33-8 Conditions to Consider in the Differential Diagnosis of Drug-Induced Sexual Dysfunction in Males

Decreased libido

- End-stage renal disease
- Hyperprolactinemia
- Moderate-severe chronic obstructive pulmonary disease
- Primary hypogonadism due to testes removal (postorchiectomy) or injury (e.g., mumps orchitis)
- Secondary hypogonadism due to hypothalamic or pituitary disorder or tumor

Erectile dysfunction

- Hormonal disorders (e.g., primary or secondary hypogonadism, hyperprolactinemia[a])
- Penile disorders (e.g., Peyronie disease, penile trauma, previous priapism, congenital penile anomalies, such as hypospadias)
- Psychiatric disorders (e.g., depression, schizophrenia, performance anxiety)
- Neurologic disorders (e.g., diabetes mellitus, spinal cord injury, stroke, postradical prostatectomy, postpelvic trauma with pelvic nerve injury, chronic alcoholism, peripheral neuropathy, Parkinson disease)
- Vascular disorders (e.g., hypertension, arteriosclerotic cardiovascular disease, peripheral vascular disease)

Ejaculation disorder

- If anejaculation, long-standing diabetes mellitus, radical prostatectomy[92]
- If premature or delayed ejaculation, performance anxiety
- If retrograde ejaculation, prostatectomy, surgical injury to the bladder neck or diabetes mellitus, pelvic surgery (e.g., aorto-iliac reconstruction, colorectal excision), neurologic illness (e.g., multiple sclerosis, autonomic neuropathy, spinal cord injury)

Priapism

- Chronic granulocytic leukemia
- Coagulopathy
- Drug abuse

- Excessive sexual activity
- Fat embolus during intravenous hyperalimentation
- Glucose-6-phosphate dehydrogenase deficiency
- Hemodialysis
- Infections mediated by toxins (e.g., scorpion sting, spider bite, rabies, malaria)
- Multiple myeloma
- Neoplasms
- Sickle cell disease
- Spinal cord injury
- Thalassemia

Infertility

- Absent or nonfunctional testes
- Cryptorchidism
- Extensive radiation therapy to pelvis
- Hyperprolactinemia
- Obstruction of epididymis or vas deferens (e.g., congenital cystic fibrosis)
- Presence of antisperm antibodies, sperm dysfunction, or decreased sperm count
- Primary or secondary hypogonadism
- Testicular cancer
- Testicular infection
- Testicular trauma

---

[a] These disorders produce decreased libido and secondary erectile dysfunction.

Patients with infertility are diagnosed with semen analysis and FSH serum concentrations. Patients with drug-induced infertility due to testicular damage present with increased FSH, azoospermia/oligospermia, decreased semen volume, abnormal sperm motility and morphology, or all of these. Antineoplastic chemotherapy is one of the most common causes of infertility. The usual onset is 8–12 weeks after the start of chemotherapy. The incidence and duration of infertility are greater with the use of alkylating agents in high doses in repeated cycles, which are associated with extensive damage to spermatogonia.[174] Recovery of fertility is dependent on the number of remaining functional spermatogonia after chemotherapy. Significant delays in recovery, up to several years after the last dose of chemotherapy, are due to extensive reduction in the numbers of spermatogonia and stem cells.[140]

RISK FACTORS

Specific risk factors for drug-induced sexual dysfunction in males have been proposed but not confirmed. Possible risk factors for drug-induced sexual dysfunction in males are listed in **Table 33-9**. Several factors associated with diminished sexual function include age >40 years, smoking, drinking excessive amounts of alcohol, cardiovascular disease, hypertension, diabetes mellitus, spinal cord injury, stroke, cancer, and mental depression or other psychiatric illness.[177,178] In addition, the risk of drug-induced sexual dysfunction is greater in patients taking combinations of drugs known to cause sexual dysfunction. In all patients with sexual dysfunction, independent of the etiology, elimination of these risk factors and/or treatment of underlying diseases that could contribute to sexual dysfunction is always recommended.

MORBIDITY AND MORTALITY

Except for priapism, drug-induced sexual dysfunction is largely a benign disease.[179] Patient morbidity is largely related to the negative impact of drug-induced sexual dysfunction on the quality of life of affected patients and their partners.[180,181] Depression, performance anxiety, and lack of self-confidence or diminished self-esteem can result. Priapism can be painful.

Decreased libido, erectile dysfunction, and ejaculatory disorders do not result in mortality. Some patients may not seek medical treatment for sexual dysfunction, as they attribute these disorders to the natural aging process, are not sexually active or do not have a sexual partner, are embarrassed to seek treatment, or do not think the adverse effect is important (e.g., a 65-year-old male who already has many children may not be concerned about infertility).

Untreated priapism or priapism that responds poorly to drug or surgical intervention may result in penile fibrosis, which can lead to irreversible erectile dysfunction. In one rare case of papaverine-induced priapism, a pulmonary embolus developed.[172]

PREVENTION

Minimizing risk factors associated with drug-induced sexual dysfunction may prevent the disease (Table 33-9). Drugs known to cause sexual dysfunction should be avoided in young, sexually active males, if possible. If this is not possible, these drugs should be used at the lowest effective dose for the shortest period of time.

Table 33-9 Risk Factors for Drug-Induced Sexual Dysfunction in Males[13,150,169,177-179]

Vascular risk factors

- Arteriosclerotic cardiovascular disease
- Hyperlipidemia
- Hypertension
- Peripheral vascular disease
- Sickle cell anemia
- Smoking

Neurologic risk factors

- Chronic alcohol use
- Diabetes mellitus
- Parkinson disease, various causes
- Pelvic trauma with nerve injury
- Postradical prostatectomy or retroperitoneal surgery
- Spinal cord injury
- Stroke

Hormonal risk factors

- Hyperprolactinemia
- Hyperthyroidism
- Hypothyroidism
- Primary or secondary hypogonadism

Psychogenic risk factors

- Anxiety disorder
- Depression
- Psychosis
- Strained relationship with significant other

Other risk factors

- Cancer
- Kidney failure
- Liver failure
- Obesity
- Penile disorder (e.g., Peyronie disease, penile injury, penile fracture)
- Poor physical health
- Recreational drug abuse
- Respiratory failure

Comorbid conditions that have been associated with sexual dysfunction should be treated optimally (Table 33-8). Lifestyle modifications, such as smoking cessation, weight loss, and avoidance of excessive alcohol use (which decreases libido and secondarily produces erectile dysfunction) should be implemented, if necessary. Often, optimal treatment of an underlying condition that could be contributing to erectile dysfunction can help reduce the sexual disorder.[182] Taking complete and careful medical and medication histories is important so that unnecessary medications can be discontinued. This should be followed by evaluation of pertinent physical examination findings. Laboratory tests, such as measurement of serum testosterone concentrations and semen analyses, should not be obtained routinely in patients for whom a drug is prescribed that has been associated with sexual dysfunction; such laboratory tests should be obtained only if the patient has a medical history and symptoms that are consistent with drug-induced sexual dysfunction. **Table 33-10** describes a general approach to prevent drug-induced sexual dysfunction and infertility.

Table 33-10 Approaches to Help Prevent Drug-Induced Sexual Dysfunction in Males

- Maintain heart-healthy lifestyle: do not smoke, avoid excessive alcohol, maintain ideal body weight, and exercise regularly.[150,177,178]
- If patient has hypertension, diabetes mellitus, or depression, he should optimize treatment of these conditions.
- If the patient is older than 50 yr of age, he should undergo an annual urologic evaluation to check for genitourinary tract disorders (e.g., benign prostatic hypertrophy, prostate cancer) that could affect sexual function.
- If the patient will need to take a medication that may cause sexual dysfunction or infertility, the healthcare professional should consider any of the following measures: if possible, to minimize the risk of drug-induced sexual dysfunction: use the lowest effective dose of the medication, change the timing of the medication so that the peak serum concentration does not occur when the patient wants to be sexually active (this works for medications with short half-lives or that cause sedation), or switch the patient from a medication with a higher prevalence of sexual dysfunction to a medication with a lower prevalence of sexual dysfunction.

It has been suggested that prescribers can choose medications that are less likely to cause sexual dysfunction for sexually active patients. Published literature is available for a limited number of pharmacologic categories of medications. For example, among the antipsychotic agents, olanzapine, aripiprazole, and quetiapine appear to cause less sexual dysfunction than risperidone.[91,191] Among the antihypertensives, angiotensin II-receptor antagonists, angiotensin-converting enzyme inhibitors, and calcium antagonists appear to cause less sexual dysfunction than thiazide diuretics, sympatholytics, and β-adrenergic antagonists.[194] Among the antidepressants, bupropion, mirtazapine, nefazodone, and vilazodone appear to cause less sexual dysfunction than sertraline, venlafaxine, citalopram, paroxetine, fluoxetine, imipramine, phenelzine, duloxetine, escitalopram, and fluvoxamine.[40,79,157,175] Among the anticonvulsants, levetiracetam and topiramate appear to cause less sexual dysfunction than other agents.[50] However, it is important to recognize that literature comparing the frequency of sexual dysfunction among agents in the same pharmacologic category includes many poorly designed research studies; most are not randomized controlled trials, standardized definitions of sexual dysfunction were not used, patient sample sizes are small, and study results often conflict with one another. Also, in some patient cases, choosing an agent with a lower propensity to cause sexual dysfunction may not be possible, as the patient's underlying medical illness may not respond to the medication.

MANAGEMENT

Treatment options for the management of drug-induced sexual dysfunction are presented in **Table 33-11**. When drug-induced sexual dysfunction occurs and the patient seeks treatment, it is recommended that the causative agent be discontinued or stopped temporarily (drug holiday). After an adequate washout period, the patient should be reassessed to determine whether sexual dysfunction is still present. If the offending agent cannot be discontinued, dose reduction is often helpful. Alternatively, replacing the causative agent with a drug that is associated with a lower likelihood of causing sexual dysfunction could be considered.[190,191] However, as mentioned in the section "Prevention," this strategy may not be effective and could compromise treatment of an underlying medical condition that requires treatment. For certain types of drug-induced sexual dysfunction, specific treatments have been described in the literature. However, in many cases, no direct comparison studies have been performed to determine whether one specific treatment is more effective than another. In addition, implementation of drug therapy to treat a disease caused by another drug is never a preferred management approach, as it adds to the patient's drug costs and is usually associated with additional adverse effects. Pharmacotherapy for the purpose of treating sexual dysfunction induced by another drug should be implemented only when other measures fail or are not feasible.

Table 33-11 Approaches to Manage Drug-Induced Sexual Dysfunction in Males

In all cases of drug-induced sexual dysfunction, management should include the following:

- Temporarily holding (drug holiday), discontinuing, or reducing dose of offending agent, if possible
- Switching to another drug that does not cause or is less likely to cause sexual dysfunction, if possible
- Initiating a specific drug to treat sexual dysfunction only if first two steps do not work or cannot be implemented

Type of Dysfunction	Additional Management Approaches
Decreased libido	• Psychotherapy or counseling • If patient has low serum testosterone concentration, consider testosterone supplementation (e.g., testosterone cypionate or testosterone enanthate 200 mg intramuscularly q 3–4 wk), provided the patient has no contraindications.[150,165]
Erectile dysfunction	• Initiate a phosphodiesterase type 5 inhibitor (e.g., sildenafil 50–100 mg orally 1 hr before sexual intercourse; vardenafil 10–20 mg orally [Levitra] or 10 mg on the tongue [Staxyn] 1 hr before sexual intercourse; tadalafil 10–20 mg orally 30 min before sexual intercourse or 2.5–5 mg daily; or avanafil 100–200 mg orally 15 min before sexual intercourse). • If oral agents are unsuccessful or contraindicated, initiate intracavernosal alprostadil (e.g., alprostadil 10 mcg intracavernosally 30 min before intercourse) or intraurethral alprostadil 125–250 mcg 30–60 min before intercourse. • If oral agents are unsuccessful or contraindicated, initiate use of a vacuum erection device. • Surgical implantation of a penile prosthesis is a treatment of last resort; it is highly effective but is associated with more potential adverse effects than medical treatments.

	• The American Urological Association has published guidelines on management of erectile dysfunction[183]; other management guidelines have been published.[175,179,184]
Ejaculation disorder	• If retrograde ejaculation or emission failure, initiate imipramine 25–50 mg daily for 7 days prior to planned sexual activity, or pseudoephedrine 60 mg 1 hr prior to planned sexual activity.[91,92] • For anejaculation, penile vibratory stimulation, rectal probe electroejaculation, or direct microsurgical sperm harvesting has been employed.[92] • If premature ejaculation, psychotherapy or other self-control techniques may be useful. Alternatively, manual squeezing of the glans penis to stop ejaculation may be helpful[174]; alternatively, application of 2% lidocaine jelly or lidocaine 2.5%/prilocaine 2.5% cream (EMLA) to the glans penis 20–30 min before coitus may decrease sensitivity of penis to tactile stimulation; however, a condom should be applied after topical application to prevent inadvertent exposure to female partner[186]; administration of sertraline 25–200 mg orally daily, paroxetine 10–40 mg orally daily, fluoxetine 5–20 mg orally daily, or clomipramine 25–50 mg orally daily for 1 or 2 wk, which produces anejaculation, has been used with some success[6,91,157,185]; these agents have also been dosed as an episodic regimen, several hours before sexual intercourse, instead of daily.[186] The American Urological Association has published guidelines on management for premature ejaculation[186]; other published recommendations are available for ejaculation disorders.[80,91,92,187]
Priapism	• Sedate patient to reduce central nervous system stimulation that might be causing or exacerbating priapism. • Put the patient in a quiet, darkened room. • Apply ice packs to the penis. • Aspirate and irrigate sludged blood from corpora, if necessary. • If due to excessive use of intracavernosal alprostadil, can use intracavernosal phenylephrine (100–500 mcg/mL) 1 mL q 3–5 min until detumescence occurs. • Initiate surgical arteriovenous shunts of the corpora as a treatment of last resort. • The American Urological Association has published guidelines on management of priapism[188]; other published recommendations are available.[115,172,192]
Infertility	• Reassure the patient that after a significant time after the last dose of chemotherapy, fertility may return; however, the time to recovery is highly dependent on the degree of damage to the germinal cells; if the patient is receiving antineoplastic chemotherapy for cancer, the benefit of continuing treatment outweighs the risk of this adverse effect.[174] • Sometimes, this adverse effect can be minimized by using lower doses of drugs in combination and using combinations of drugs with a lower potential to cause infertility. • Although a variety of hormonal therapies have been tried (e.g., testosterone supplements, clomiphene citrate, human chorionic gonadotropin), none has been uniformly effective.

	• The American Urological Association has published guidelines on the diagnosis and management of infertility[189]; other published recommendations are available.[173,174]

INFORMATION FOR PATIENTS

Practitioners who counsel patients with drug-induced sexual dysfunction should have a clear understanding of the categories of sexual dysfunction so that there is no confusion in discussing the specific problem with the patient.[29] Patients should be advised that drug-induced sexual dysfunction (with the exception of alkylating agent-induced infertility) is usually reversible following discontinuation of the culprit drug. Patients who are taking drugs that may cause sexual dysfunction should be counseled regarding the specific type(s) of dysfunction that could occur and the specific symptoms that may result. Patients should be advised to implement lifestyle changes (e.g., quitting smoking, reducing alcohol consumption, losing weight if obese) that may minimize the risk of drug-induced sexual dysfunction. Patients should be instructed to consult their healthcare provider if sexual dysfunction that interferes with their lifestyle or negatively impacts their quality of life occurs. Patients should be instructed to avoid using nonprescription medications, illicit drugs, and some herbal medicines, including those that may cause sedation, produce anticholinergic effects, have antiandrogenic effects, or inhibit hepatic metabolism of the offending drug, as these factors can worsen the degree of drug-induced sexual dysfunction. In addition, patients should inform the healthcare provider of any new medications so that these can be checked for interactions with existing medications that may cause or exacerbate drug-induced sexual dysfunction. If the patient has risk factors for priapism (e.g., the patient has sickle cell anemia or is using erectogenic drugs), he should be instructed to seek medical attention immediately if an erection persists for 4 hours or more. Because extensive radiation therapy and chemotherapy for cancer may cause irreversible damage to the testes and infertility, patients should be advised to bank semen before chemotherapy. After chemotherapy, to minimize teratogenic effects due to persistent drug-induced mutations to sperm, patients should be advised to delay conception for 6 months to 2 years after the last dose of chemotherapy.[174,193]

Practitioners caring for patients with drug-induced sexual dysfunction should talk to these patients, respond to their questions, and anticipate their concerns. These cases must be handled with the utmost confidentiality. Counseling should take place in a quiet, secure area. The practitioner should project an attitude of caring and respect and be nonjudgmental in handling the patient's issues.

Some patients find it difficult to discuss their concerns regarding drug-induced sexual dysfunction. Practitioners can be helpful and proactive. For example, pharmacists can initiate a follow-up consultation session when refilling a prescription by stating, “This medication may cause changes to your sexual function when used in usual doses. Has this been a problem for you?” Such a statement immediately puts the patient at ease because the patient is reminded up front that the problem is not unique and occurs commonly. Also, some patients who experience drug-induced sexual dysfunction may refuse to continue to take necessary medications. In this case, the pharmacist should discuss the benefits and risks of taking the medication, notify the prescriber of the problem, and offer options for management of the patient’s primary problem and for his drug-induced sexual dysfunction.

CHAPTER 34

Gynecologic Diseases and Infertility in Women

Judith A. Smith

Drug-induced gynecologic diseases and infertility in women can have an enormous impact on the quality of life for those afflicted. The true incidence of drug-induced gynecologic diseases, dysfunctions, and disorders is difficult to estimate because of significant underreporting. The drug-induced gynecologic diseases have an insidious and inconsistent onset that can make prevention and diagnosis a challenge. Moreover, women often do not identify the relationship between the use of the offending agent and the onset of the gynecologic disease, dysfunction, or condition. Although appropriate interventions often can successfully manage and relieve the symptoms associated with the various drug-induced gynecologic diseases discussed in this chapter, some will result in irreversible outcomes such as sexual dysfunction or infertility. There is a need to continue research in the women's health arena particularly to advance the management and prevention of the drug-induced gynecologic disorders addressed in this chapter.

OVARIAN HYPERSTIMULATION

CAUSATIVE AGENTS

Drug-induced ovarian hyperstimulation occurs after repeated or prolonged use of ovulation-induction agents such as antiestrogens (clomiphene citrate or tamoxifen), gonadotropins (gonadorelin, human chorionic gonadotropin [hCG]), or gonadotropin-releasing agonists (goserelin acetate). Drugs implicated in ovarian hyperstimulation are listed in **Table 34-1**.[1-36]

EPIDEMIOLOGY

Ovulation-induction medications were introduced over 40 years ago. Drug-induced ovarian hyperstimulation has been reported to occur in up to 27.7% of patients receiving ovulation-induction drugs, with severe cases occurring in <2% of patients.[3-6]

Table 34-1 Agents Implicated in Drug-Induced Gynecologic Diseases and Infertility in Women

Drug	Incidence	Level of Evidence[a]
OVARIAN HYPERSTIMULATION[1-36,b]		
Clomiphene citrate	NK	B
Gonadotropins	NK	B
Gonadotropin-releasing agonists	NK	B
Tamoxifen	NK	C
VULVOVAGINAL CANDIDIASIS[37-42,c]		
Antibiotics (systemic)	NK	B
Corticosteroids	NK	C
Hormone-replacement therapy	NK	C
Oral contraceptives	NK	C
Tamoxifen	NK	C
VAGINAL BLEEDING DISORDERS: AMENORRHEA/OLIGOMENORRHEA[55-61]		
Antiepileptic drugs	12–59%	B
Antihypertensive agents	NK	C
Platinum analogues	>60%	B
Chlorambucil	NK	C
Alkylating agents	>60%	A
Danazol	>50%	C
Doxorubicin	>60%	B

Estrogen	NK	C
Etoposide	>60%	B
Goserelin	NK	C
Medroxyprogesterone	NK	C
Methyldopa	NK	C
Oral contraceptives	NK	C
Progesterone	NK	C
Spironolactone	NK	C
Tamoxifen	NK	C
Thalidomide	NK	C
VAGINAL BLEEDING DISORDERS: MENORRHAGIA/MENOMETRORRHAGIA[81-88]		
Ginseng	NK	C
Human relaxin	NK	C
Levonorgestrol–intrauterine contraceptive devices	2–4%	A
Methadone	>50%	B
Selective serotonin reuptake inhibitors	<1%	B
VAGINAL BLEEDING DISORDERS: DYSMENORRHEA[102,d]		
Estrogen	NK	C
Oxytocin	NK	C
Progesterone	NK	C
Vasopressin	NK	C
SEXUAL DYSFUNCTION[109-112,117-122]		
Antiepileptic drugs	NK	C
Antihypertensive agents	11%	B
Antidepressants	16–57%	B
Antipsychotics	28–93%	B
Amphetamines	NK	C
Baclofen	NK	C
Bromocriptine	NK	C
Cimetidine	NK	C
Digoxin	NK	C
Granisetron	NK	C
Indinavir	40%	C
Ketamine	NK	C
Methadone	NK	C
Methazolamide	NK	C
Naproxen	NK	C

Norethandrolone	NK	C
INFERTILITY[131-144]		
Alkylating agents	<60%	A
Antiepileptic drugs	12–59%	B
Anthracyclines	<60%	B
Bleomycin	<60%	C
Caffeine	NK, dose-dependent	A
Etoposide	<60%	B
Fluorouracil	<60%	B
Methotrexate	<60%	A
Platinum analogues	<60%	B
Thalidomide	<60%	A
Vinca alkaloids	<60%	C

NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Occurs in up to 27.7% of patients receiving ovulation-induction drugs, with severe cases occurring in less than 2% of patients.

[c] Approximately 17–39% of gynecologic office visits are associated with cases of vulvovaginal candidiasis.

[d] The incidence of dysmenorrhea in menstruating women ranges from 3–90%.

MECHANISMS

Gonadotropins or gonadotropin-releasing agonists are used in the follicular phase of the ovarian cycle to increase serum concentrations of follicle-stimulating hormone (FSH) and luteinizing hormone (LH), for the purpose of increasing the maturation of multiple ovarian follicles resulting in multiple ovulations.[7] Antiestrogen agents interact with estrogen receptors at the hypothalamus, displacing endogenous estrogen, thereby disrupting the endogenous estrogen negative feedback loop effect.[7] Ultimately, this results in stimulation of the release of FSH and LH, increasing the maturation of multiple ovarian follicles, producing multiple ovulations. Endogenous and exogenous hCG (or both) also likely contribute to the pathogenesis of ovarian hyperstimulation.[8] It is believed that hCG stimulates continuous ovulation, and it may also increase ovarian capillary permeability.[8] Mechanisms of drug-induced ovarian hyperstimulation are described in **Table 34-2**.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Signs and symptoms associated with ovarian hyperstimulation are listed in **Table 34-3**. This drug-induced disease may occur either early (within 7 days) or late (within 7–14 days) after initiation of drug therapy. The primary sign of ovarian hyperstimulation is significant enlargement of the ovary that leads to the leakage of protein-rich fluid from ovarian capillaries into the peritoneal space.[9] Drug-induced ovarian hyperstimulation may be associated with multiple nonspecific symptoms related to the accumulation of this peritoneal fluid and including abdominal distention, pain or a pulling sensation in the pelvis, nausea, vomiting, diarrhea, pleural effusions, dyspnea, or chest pain.[4] In addition to ovary enlargement, specific signs suggestive of ovarian hyperstimulation include ascites, oliguria, tachycardia, and, in severe cases, pleural effusion.[6,11] These signs and symptoms of drug-induced ovarian hyperstimulation must be differentiated from other conditions that may result in similar symptoms, such as gastrointestinal complications of ovarian cysts, endometriosis, and ectopic pregnancy. Conditions to consider in the differential diagnosis of ovarian hyperstimulation are presented in **Table 34-4**.

RISK FACTORS

Specific risk factors for the development of drug-induced ovarian hyperstimulation are not well established. Those that are known are listed in **Table 34-5**. Younger patients tend to be at higher risk because they have a larger number of recruitable follicles and gonadotropin receptors.[11,12] Although some data suggest that women with a history of polycystic ovarian syndrome may have an increased risk for drug-induced ovarian hyperstimulation, in most cases this drug-induced disease is not predictable.[13-16] Repeated or prolonged cycles of clomiphene citrate and gonadotropins as well as high doses contribute to an increased risk of drug-induced ovarian hyperstimulation.[17-21]

MORBIDITY AND MORTALITY

Early or mild drug-induced ovarian hyperstimulation typically resolves without intervention and with no significant sequelae. However, severe cases of drug-induced ovarian hyperstimulation or cases that are diagnosed late can be life-threatening.[4] In the short term, the fluid shifts can result in significant ascites, intravascular volume depletion, and pleural effusion that may lead to significant breathing difficulties and, in rare cases, acute respiratory distress syndrome. Ascitic fluid can put pressure on the inferior vena cava and lead to decreased cardiac output.[4] Severe cases of drug-induced ovarian hyperstimulation have been associated with significant thromboembolic events.[5,6] In addition, patients are at risk of ovarian torsion or cyst rupture that may potentially lead to hemorrhage with fatal outcomes.[5,6] Finally, although it is controversial if a truly causative relationship, ovarian hyperstimulation from use of fertility drugs has been associated with the development of ovarian cancer.[18-29]

PREVENTION

A few measures may prevent drug-induced ovarian hyperstimulation, including suspending the treatment cycle of the offending agent, extending the interval between treatments with the offending agent, planning early follicular aspiration, or administration of albumin or concomitant progesterone therapy (**Table 34-6**).[3,5,6] Patients should be monitored closely while undergoing any type of ovarian stimulation therapy with serum estradiol concentrations obtained prior to initiating each new cycle of treatment as well as after completion of each cycle and ultrasound performed at baseline and at least once after each treatment cycle. If serum estradiol concentrations increase rapidly at any time during the treatment or if ultrasound reveals massive follicle recruitment, one of the interventions described above should be undertaken to prevent the development of drug-induced ovarian hyperstimulation.[30] In patients at increased risk for drug-induced ovarian hyperstimulation, a lower dose of hCG (5,000 international units instead of the standard 10,000 international units) may be administered. Alternatively, exogenous progesterone (50 mg intramuscularly, 100 mg intravaginal suppository, or 8% intravaginal gel) may be administered in place of additional doses of hCG to support the luteal phase.[30,31] Another option is the intravenous administration of 25% albumin during follicular aspiration; however, the effectiveness of this approach for prevention of drug-induced ovarian hyperstimulation has been variable.[30,32-34]

Table 34-2 Mechanisms of Drug-Induced Gynecologic Diseases and Infertility in Women

Drug	Mechanism
OVARIAN HYPERSTIMULATION[1-36]	
Clomiphene citrate	Disrupts endogenous estrogen negative feedback loop at the hypothalamic level by blocking estrogen receptors inducing ovulation
Gonadotropins	Increase FSH and LH inducing multiple ovulations
Gonadotropin-releasing agonists	Increase FSH and LH inducing multiple ovulations

Tamoxifen	Disrupts endogenous estrogen negative feedback loop at the hypothalamic level by blocking estrogen receptors inducing ovulation
VULVOVAGINAL CANDIDIASIS[37-46]	
Antibiotics (systemic)	Alter normal flora (lactobacilli) of vagina resulting in overgrowth of *Candida*
Corticosteroids	Increase glycogen content, increasing pH and promoting growth of *Candida*
Hormone-replacement therapy	Increases glycogen content, increasing pH and promoting growth of *Candida*
Oral contraceptives	Increase glycogen content, increasing pH and promoting growth of *Candida*
Tamoxifen	Increases glycogen content, increasing pH and promoting growth of *Candida*
VAGINAL BLEEDING DISORDERS: AMENORRHEA/OLIGOMENORRHEA[55-61]	
Antiepileptic drugs	Increase hormone-binding globulin, resulting in decreased binding of estradiol leading to ovarian dysfunction
Antihypertensive agents	Microvascular instability inducing breakthrough bleeding
Alkylating agents and platinum analogues	Direct toxic effects on oocytes that halts ovulation, inducing amenorrhea
Chlorambucil	Direct toxic effects on oocytes that halts ovulation, inducing amenorrhea
Danazol	Indirect inhibition of negative feedback loop of the hypothalamic–pituitary pathway, decreasing FSH/LH release and altering ovarian function
Doxorubicin	Direct toxic effects on oocytes that halts ovulation, inducing amenorrhea
Estrogen	Indirect inhibition of negative feedback loop of the hypothalamic–pituitary pathway, decreasing FSH/LH release and altering ovarian function
Etoposide	Direct toxic effects on oocytes that halts ovulation, inducing amenorrhea
Goserelin	Indirect inhibition of negative feedback loop of the hypothalamic–pituitary pathway, decreasing FSH/LH release and altering ovarian function
Medroxyprogesterone	Direct effect on uterine lining
Methyldopa	Increases prolactin concentrations; indirect effect on LH secretion
Oral contraceptives	Indirect inhibition of negative feedback loop of the hypothalamic–pituitary pathway, decreasing FSH/LH release and altering ovarian function
Progesterone	Indirect inhibition of negative feedback loop of the hypothalamic–pituitary pathway, decreasing FSH/LH release and altering ovarian function

Spironolactone	Microvascular instability, inducing breakthrough bleeding
Tamoxifen	Indirect inhibition of negative feedback loop of the hypothalamic–pituitary pathway, decreasing FSH/LH release and altering ovarian function
Thalidomide	Direct toxic effects on oocytes that halts ovulation, inducing amenorrhea
VAGINAL BLEEDING DISORDERS: MENORRHAGIA/MENOMETRORRHAGIA[81-88]	
Ginseng	Unknown
Human relaxin	Induction of vascular endothelial growth factor receptor
Levonorgestrol–intrauterine contraceptive devices	Unknown; possible changes in prostaglandin concentrations in uterine tissue
Methadone	Unknown
Selective serotonin reuptake inhibitors	Decreased clotting function
VAGINAL BLEEDING DISORDERS: DYSMENORRHEA[102]	
Estrogen	Rapid fluctuations in serum hormone concentrations; activation of inflammation cascade leading to pelvic swelling and pain
Oxytocin	Antidiuretic effect that alters uterine contractions to dysrhythmic and painful pattern
Progesterone	Rapid fluctuations in serum hormone concentrations; activation of inflammation cascade leading to pelvic swelling and pain
Vasopressin	Antidiuretic effect that alters uterine contractions to dysrhythmic and painful pattern
SEXUAL DYSFUNCTION[109-112,117-122]	
Antiepileptic drugs	Increase serum concentrations of hormone-binding globulin, decreasing estradiol binding and altering the hypothalamic–pituitary axis regulation of hormone release
Antihypertensive agents	Decrease vaginal lubrication; decrease libido via antiandrogenic and antidopaminergic activity
Antidepressants	Loss of libido and orgasm dysfunction by altering central serotonergic activity that disrupts hypothalamic–pituitary axis regulation of hormone release
Antipsychotics	Elevate prolactin concentrations via inhibition of dopamine-2 receptors, which decreases libido and disrupts orgasms
Amphetamines	Loss of libido and orgasm dysfunction by altering central serotonergic and dopaminergic activity and, indirectly, hypothalamic–pituitary axis regulation of hormone release
Baclofen	Proposed to be associated with inhibitory effects of GABA_B receptors

Bromocriptine	Elevates prolactin concentrations, which decreases libido and disrupts orgasms
Cimetidine	Antiandrogenic effects
Digoxin	Disrupts hypothalamic–pituitary axis regulation of hormone release
Granisetron	Unknown
Indinavir	Unknown
Ketamine	Unknown; possible dissociation effects, altered muscle tone
Methadone	Decrease in lutenizing hormone production and subsequent testosterone concentrations
Methazolamide	Unknown
Naproxen	Unknown
Norethandrolone	Disrupts hypothalamic–pituitary axis regulation of hormone release
INFERTILITY131-144	
Alkylating agents	Direct toxic effect on oocytes, permanently halt ovulation
Antiepileptic drugs	Increase serum concentrations of hormone binding globulin decreasing estradiol binding and decreasing/halting ovarian function
Anthracyclines	Direct toxic effect on oocytes, permanently halts ovulation
Bleomycin	Direct toxic effect on oocytes, permanently halts ovulation
Caffeine	Unknown
Etoposide	Direct toxic effect on oocytes, permanently halts ovulation
Fluorouracil	Direct toxic effect on oocytes, permanently halts ovulation
Methotrexate	Direct toxic effect on oocytes, permanently halts ovulation
Platinum analogues	Direct toxic effect on oocytes, permanently halts ovulation
Thalidomide	Direct toxic effect on oocytes, permanently halts ovulation
Vinca alkaloids	Direct toxic effect on oocytes, permanently halts ovulation

LH = luteinizing hormone, FSH = follicle-stimulating hormone.

Table 34-3 Signs and Symptoms Associated with Drug-Induced Gynecologic Diseases and Infertility in Women

Ovarian hyperstimulation

- Abdominal distention
- Ascites
- Chest pain
- Diarrhea
- Dyspnea
- Enlargement of ovary
- Nausea and vomiting
- Pelvic pain

Vulvovaginal candidiasis

- Dyspareunia
- Vaginal erythema
- Vaginal pruritus
- Vaginal swelling (edema)
- White, curd-like vaginal discharge

Vaginal bleeding disorders

- Amenorrhea and oligomenorrhea
  - Decreased cervical mucus
  - Dyspareunia
  - Irregular menses
  - Irritability
  - Mood swings
  - No menses
  - Vaginal dryness
  - Vaginal wall thinning
- Menorrhagia and menometrorrhagia
  - Heavy menses (>80 mL)
  - Irregular menses
  - Prolonged menses
  - Uterine fibroids
  - Uterine polyps
- Dysmenorrhea
  - Abdominal cramping
  - Backache
  - Bloating
  - Breast tenderness
  - Fatigue
  - Headache
  - Mood changes
  - Nausea
  - Pelvic pain
  - Syncope
  - Vomiting

Sexual dysfunction

- Anger or fear
- Anxiety
- Dyspareunia
- Fatigue
- Loss of libido or desire (may present as depression)

- Vaginismus
- Frequent/recurrent miscarriages
- Inability to conceive
- Irregular menses
- No menses

Infertility

- Frequent/recurrent miscarriages
- Inability to conceive
- Irregular menses
- No menses

MANAGEMENT

Treatment options for drug-induced ovarian hyperstimulation are described in **Table 34-7**. Mild cases in which patients present with some discomfort and for which the only physical finding is mild abdominal distention will resolve without any intervention.[4] Fluid shifts can occur because of significant ascites, intravascular volume depletion, and pleural effusions. To help prevent progression and adverse sequelae related to these fluid shifts, patients should be instructed to increase fluid intake. Patients with moderate drug-induced ovarian hyperstimulation often present with increasing abdominal girth, pain, nausea and vomiting, diarrhea, shortness of breath, or any combination of these. Moderate ovarian hyperstimulation can be treated on an outpatient basis, but close monitoring and follow-up are required. These patients should be instructed to increase oral hydration and may benefit from a short course of intravenous hydration. Outpatients with moderate drug-induced ovarian hyperstimulation should be on strict bed rest and should monitor oral intake, weight, and urine output. Short-term use of antiemetic agents and analgesics can be used to alleviate nausea and mild pelvic pain. The administration of a gonadotropin-releasing–hormone agonist (intramuscular leuprolide 7.5 mg once monthly) has been reported to be successful for the treatment of tamoxifen-induced ovarian hyperstimulation.[35]

Table 34-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Gynecologic Diseases and Infertility in Women

Ovarian hyperstimulation

- Endometriosis
- Ectopic pregnancy
- Ovarian cysts

Vulvovaginal candidiasis

- Bacterial vaginosis
- Chlamydia
- Gonorrhea
- Trichomoniasis
- Urinary tract infection

Vaginal bleeding disorders

- Amenorrhea and oligomenorrhea
  - Anorexia nervosa
  - Endocrine disorders
  - Excessive physiological stress
  - Excessive psychological/emotional stress
  - Hypothalamus tumor
  - Metabolic disorders
  - Pituitary tumor
- Menorrhagia and menometrorrhagia
  - Abnormal endometrial hyperplasia
  - Endometrial cancer
  - Endometriosis
  - Fibroids
  - Uterine polyps
- Dysmenorrhea
  - Premenstrual syndrome

Sexual dysfunction

- Anxiety/anger or fear
- Depression
- Dyspareunia
- Fatigue

Infertility

- Early menopause
- Endocrine disorder
- Metabolic disorder

Table 34-5 Risk Factors for Drug-Induced Gynecologic Diseases and Infertility in Women

Ovarian hyperstimulation

- Polycystic ovarian syndrome
- Younger age

Vulvovaginal candidiasis

- Diabetes
- Heat/moisture
- History of vulvovaginal candidiasis
- Obesity
- Pregnancy

- Tight clothing

Vaginal bleeding disorders

- Amenorrhea and oligomenorrhea
  - Advancing age
  - Anorexia
  - Excessive exercise
  - Perimenopause
  - Poor nutritional status
  - Psychological (i.e., work/family/school) stress
- Menorrhagia and menometrorrhagia
  - Unknown
- Dysmenorrhea
  - Early menarche
  - Family history
  - Heavy menses
  - High omega-6 fatty acid diets

Sexual dysfunction

- Depression
- Hypogonadism
- Hypothyroidism
- Hysterectomy
- Oophorectomy
- Schizophrenia
- Vulvovaginal resection

Infertility

- Autoimmune diseases
- Endocrine disorders
- Epilepsy
- Older age

Table 34-6 Approaches to Help Prevent Drug-Induced Gynecologic Diseases and Infertility in Women

Ovarian hyperstimulation

- Add progesterone to treatment cycle
- Extend interval between treatment cycles
- Monitor serum estradiol concentrations
- Perform pelvic ultrasound
- Plan early follicular aspiration
- Suspend treatment cycle

Vulvovaginal candidiasis

- Consume acidophilus/yogurt with activated cultures
- Take prophylactic antifungal treatment when taking systemic antibiotics
- Wear loose clothing and cotton undergarments

- Wipe away from vulvovaginal area after bowel movement

Vaginal bleeding disorders

- Amenorrhea and oligomenorrhea
  - Eat a well-balanced diet and exercise
  - Monitor the duration and frequency of menses episodes
  - Preserve ovarian function during cytotoxic exposure (i.e., oral contraceptives)
- Menorrhagia and menometrorrhagia
  - Avoid aspirin use
  - Monitor for early indirect signs/symptoms
  - Anemia
  - Monitor for low hemoglobin
  - Monitor serum iron concentrations
  - Use iron-replacement therapy
  - Increasing duration of menses
  - Consider use of oral contraceptives to reduce irregular bleeding
- Dysmenorrhea
  - Avoid uterine stimulants (oxytocin, vasopressin)
  - Prophylactic use of anti-inflammatory agents (nonsteroidal anti-inflammatory drugs, cyclooxygenase-2 inhibitors)

Sexual dysfunction

- Identify and manage contributing symptoms (i.e., vaginal dryness)
- Offer alternative drug therapy options
- Provide education to prepare patient
- Provide resources for development of communication/coping skills for couples

Infertility

- Counsel patient and provide support resources
- Decrease consumption of caffeine-containing beverages
- Offer interventions prior to initiation of offending agent
  - Oocyte collection
  - Frozen embryos
  - Provide patient education
  - Consider use of oral contraceptives to halt ovulation during treatment with offending agent

Patients with life-threatening cases of ovarian hyperstimulation present with significant ascites, intravascular volume depletion, possible pleural effusions, severe hemoconcentration, potential renal failure, risk for acute respiratory distress syndrome, or thromboembolic events. Hospital admission with immediate intervention is required. Aggressive intravenous fluid hydration is needed in patients with severe cases of drug-induced ovarian hyperstimulation characterized by dehydration with a hematocrit>45%.[4] The rate of infusion should be adjusted to maintain urine output >30 mL/hr. All diuretics, antihistamines, angiotensin-converting enzyme inhibitors, and nonsteroidal anti-inflammatory drugs (NSAIDs) should be discontinued or avoided to prevent future volume depletion. Once the patient's condition has been stabilized, paracentesis is used, if necessary, to remove ascites fluid to alleviate pelvic pain and dyspnea. Because these patients are at risk for thromboembolic events, anticoagulation therapy with heparin (5,000 units subcutaneously every 12 hours) or low-molecular-weight heparin (e.g., enoxaparin 40 mg subcutaneously once daily) with or without sequential compression device therapy should be considered for the duration of the patient's confinement to bed. Surgical interventions such as unilateral oophorectomy or removal of cysts may be required to prevent ovarian torsion or cyst rupture that may lead to intraperitoneal hemorrhage.[4]

Table 34-7 Management of Drug-Induced Gynecologic Diseases and Infertility in Women

Ovarian hyperstimulation	*Vulvovaginal candidiasis*	*Vaginal bleeding disorders*	*Sexual dysfunction*	*Infertility*
IV fluids as appropriate • Diuretics (e.g., furosemide 20–40 mg PO/IV) • Antihistamines (e.g., diphenhydramine 50 mg IV q 4 hr as needed) • Bed rest • Antiemetic of choice (e.g., ondansetron 8 mg IV q 8 hr) • Analgesics (e.g., acetaminophen 500 mg q 6 hr as needed) • Gonadotropin-releasing-hormone agonist (leuprolide 7.5 mg IM once monthly) • Anticoagulation therapy (heparin 5,000 units sub-Q q 12 hr or enoxaparin 40 mg sub-Q once daily)	**Topical (intravaginal)** *Miconazole* • 2% cream 5 g daily × 7 days • 100 mg supp daily × 7 days • 200 mg supp daily × 3 days *Clotrimazole* • 1% cream 5 g daily × 7–14 days • 100 mg vaginal tablet daily × 7 days • 2–100 mg vaginal tablets daily × 3 days • 500 mg vaginal tablet × 1 day *Tioconazole* • 6.5 % ointment 5 g × 1 dose *Terconazole* • 0.4% cream 5 g daily × 7 days • 0.8 % cream 5 g daily × 3 days • 80 mg supp daily × 3 days **Oral** *Fluconazole* • 150 mg orally × 1 dose	**Amenorrhea and oligomenorrhea** • Combination oral contraceptives of preference (e.g., 35–50 mcg ethinyl estradiol with 0.5–1 mg norethindrone) **Menorrhagia and menometrorrhagia** • Combination oral contraceptives of preference (e.g., 35–50 mcg ethinyl estradiol with 0.5–1 mg norethindrone) • SSRI of choice (e.g., fluoxetine 20 mg daily or sertraline 50–100 mg daily) **Dysmenorrhea** • NSAID of choice (i.e., ibuprofen 400–800 mg q 6 hr with food or naproxen 250–500 mg twice daily as needed for pain) • Celecoxib 200 mg once daily	**Topical estrogen (intravaginal)** • Estropipate cream (0.15%) 2–4 g once daily × 21 days, 1 week off • Estradiol vaginal cream (0.01%) 2–4 g once daily × 2 wk, 2 weeks off • Conjugated estrogens cream (0.0625%) 0.5–2 g once daily × 21 days, 1 week off • Dienestrol cream (0.01%) 2–4 g once daily × 2 weeks, then 1 g 3 × weekly • Estradiol vaginal ring 0.05–0.1 mg per day; replace every 3 mo • Vaginal lubricants or moisturizers as needed • Sildenafil citrate 50 mg orally ~60 min prior to activity • Vibrator or mechanical stimulation	• Gonadotropin-releasing-hormone agonist (e.g., leuprolide 3.75 mg IM once monthly) • Oral contraceptives • Cryopreservation ◦ Embryo freezing ◦ Oocyte freezing ◦ Ovarian cortex freezing ◦ Follicle freezing

IM = intramuscular, IV = intravenous, PO = by mouth, NSAID = nonsteroidal anti-inflammatory drug, SSRI = selective serotonin reuptake inhibitor, sub-Q = subcutaneous.

When drug-induced ovarian hyperstimulation is detected early and interventions and treatment can be performed on an outpatient basis, symptoms usually resolve within 1 week.[6] In moderate-to-severe cases when the patients typically require hospitalization, complete symptom resolution may take 10 days or more.[6,36]

INFORMATION FOR PATIENTS

When planning ovarian-stimulation therapy, patients should be informed that they will need to be closely monitored. Patients should be told that if symptoms such as abdominal discomfort, shortness of breath, diarrhea, nausea, or vomiting occur, they should seek medical attention immediately.

VULVOVAGINAL CANDIDIASIS

CAUSATIVE AGENTS

Drug-induced vulvovaginal candidiasis most often results from the use of systemic antibiotics causing an alteration in the normal flora of the vaginal canal and allowing for an overgrowth of *Candida* species. Drugs associated with drug-induced vulvovaginal candidiasis are listed in Table 34-1.[37-41]

EPIDEMIOLOGY

Vaginal symptoms are one of the most common reports of women during annual gynecologic office visits.[42] Approximately 17% to 39% of these office visits are associated with cases of vulvovaginal candidiasis.[43,44] The majority of women (>75%) experience at least one case of vulvovaginal candidiasis during their lifetime, and many (up to 50%) suffer from recurrent or persistent cases of vulvovaginal candidiasis.[42,45]

MECHANISMS

An overgrowth of *Candida albicans, C. tropicalis, C. glabrata*, or *C. parapsilosis* resulting from environmental changes in the vagina that alter the natural flora causes vulvovaginal candidiasis, which is a common fungal infection.[37,44] Drug-induced vulvovaginal candidiasis results from change in the normal flora of the vaginal canal most often from the use of systemic antibiotics that causes an overgrowth of *Candida* species (Table 34-2).[37-46] Oral contraceptives, corticosteroids, and hormone-replacement therapy can increase the pH and glycogen content of the vaginal secretions, favoring *Candida* infections.[47] Retinoids such as acitretin also may alter vaginal secretions and indirectly change the natural flora of the vaginal canal.[48]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Physical symptoms of vulvovaginal candidiasis range from absent to severe. Symptoms in patients presenting with drug-induced vulvovaginal candidiasis are no different from those in patients presenting with spontaneous cases of vulvovaginal candidiasis (Table 34-3). The most common presenting symptom is vaginal pruritus, which may or may not be accompanied by a white, curd-like, thick vaginal discharge often described by patients as "cottage cheese-like." The infection typically originates in the vaginal canal and spreads to the vulva. The vulva and vaginal tissue may develop erythema, edema, or both because of local irritation and inflammation. The onset of signs or symptoms of drug-induced vulvovaginal candidiasis varies. As the infection progresses, symptoms increase and patients may report burning, soreness, and dyspareunia.

When a patient presents with these vaginal symptoms, a vaginal smear (culture) should be obtained to determine whether the symptoms are a result of bacterial vaginosis, trichomoniasis, or candidiasis.[51] Urinary tract infections should also be ruled out. Patients are often tested for gonorrhea or chlamydia, although neither has been closely associated with vaginal discharge.[50,51] Table 34-4 describes the conditions that should be considered in the differential diagnosis of drug-induced vulvovaginal candidiasis.

RISK FACTORS

A number of factors have been identified that predispose women to drug-induced vulvovaginal candidiasis (Table 34-5). These include younger age (<40 years), comorbid diseases or conditions, including diabetes, obesity, and pregnancy.[46,52] Environmental factors such as increased moisture and heat or tight clothing such as panty hose or use of panty liners or continuous use of cranberry juice may alter vaginal pH or acidophilus-containing products may alter vaginal normal flora and also increase a women's risk of drug-induced vulvovaginal candidiasis.[52] Sexual intercourse has not been reported as a means of transmission of vulvovaginal candidiasis.[45]

MORBIDITY AND MORTALITY

The majority of episodes of drug-induced vulvovaginal candidiasis are classified as "uncomplicated" and characterized by sporadic or infrequent episodes, mild symptoms, most likely caused by *Candida albicans* infection, and without any medical comorbities/complications. In these cases, symptoms typically resolve within 48–72 hours following initiation of appropriate therapy. Uncomplicated vulvovaginal candidiasis is not associated with morbidity. However, approximately 10% of cases of vulvovaginal candidiasis are more complicated and are associated with recurrent infections, significant symptoms (erythema, edema, pruritus, and dyspareunia), likely to be non-*Candida albicans* infection, and occur in the presence of significant comorbidities such as diabetes, immunosuppression, or severe medical conditions.

PREVENTION

Methods to prevent drug-induced vulvovaginal candidiasis are described in Table 34-6. Behavior modification, such as wearing loose clothing and cotton undergarments and wiping away from the vulvovaginal area after bowel movements, can help prevent episodes of drug-induced disease.[52] It has been suggested that consuming yogurt with "activated cultures" or taking *lactobacillus acidophilus* capsules to maintain the balance of the normal flora in the vaginal tract may prevent drug-induced vulvovaginal candidiasis infections when consumed short-term during a course of antibiotics.[41] Therapy with vitamin C (250 mg intravaginally for 6 days), which is available by prescription, may increase vaginal secretions and reduce infection and may help prevent drug-induced vulvovaginal candidiasis.[53] Douching with vinegar and water, yogurt, or potassium sorbate may help prevent reinfection by restoring the acidic pH to the vulvovaginal canal.[41]

For patients who routinely experience episodes of vulvovaginal candidiasis when taking systemic antibiotics, prophylactic antifungal treatment should be considered. Preventive treatment should be initiated simultaneously with the first dose of antibiotics.[45] A topical azole drug (miconazole, clotrimazole, ticonazole, terconazole) may be administered for 3–7 days as indicated, or two doses of fluconazole 150 mg may be administered 72 hours apart.[47] Measures for prevention of drug-induced vulvovaginal candidiasis may improve adherence to and completion of prescribed antibiotic regimens.[44,52]

MANAGEMENT

Drug-induced vulvovaginal candidiasis can be effectively treated with antifungal topical cream or vaginal suppositories administered for 1, 3, 7, or up to 14 days in severe cases when symptoms do not resolve after one course of treatment (Table 34-7).[45] The most common topical antifungal agents used to treat vulvovaginal candidiasis include miconazole and clotrimazole, both of which are available without a prescription in the United States, and terconazole, which is still only available by prescription in the United States.[47] For both prescription and nonprescription topical regimens, the recommended duration of treatment ranges from 1 to 7 days, depending on the dose and strength of the agent selected. The treatment cycle may be repeated if symptoms persist after one course. For complicated infections, the most effective option is a single 150 mg oral dose of fluconazole with the dose repeated after 3 days.[47] This treatment approach also requires a prescription in the United States.[45] The strategies discussed above for prevention of drug-induced vulvovaginal candidiasis may also have some benefit for treatment.

Patients with significant erythema, edema, and local irritation may require more prolonged treatment (up to 14 days) to achieve a complete response and eradication of all symptoms.[45,51] Although topical therapy provides more immediate relief of symptoms as compared with oral treatment, either route will successfully eradicate vulvovaginal candidiasis.[45,51,54]

INFORMATION FOR PATIENTS

Wearing loose clothing and cotton undergarments to limit excessive moisture to the vulva area will help reduce patients' risk of drug-induced vulvovaginal candidiasis.[51] Exposure to the *Candida* organisms can be minimized if patients remember to wipe away from the vulva area after a bowel movement.[51] Patients should seek medical attention for diagnosis of the first vulvovaginal candidiasis infection.[44,45] However, patients with recurrent drug-induced vulvovaginal candidiasis infections should learn to recognize the symptoms and begin early self-treatment with nonprescription medications.[41,44] Patients that receive fluconazole for treatment need to be reminded not to consume alcohol for a least 7 days after completing treatment.

VAGINAL BLEEDING DISORDERS

AMENORRHEA AND OLIGOMENORRHEA

CAUSATIVE AGENTS

Agents that alter hormone balance directly or indirectly are associated with drug-induced amenorrhea (cessation of menses), oligomenorrhea (irregular menses), or intermenstrual bleeding.[55-61] Drugs that are known to be toxic to actively dividing cells may induce premature or temporary ovarian failure that presents as drug-induced amenorrhea/oligomenorrhea.[56] For example, drug-induced amenorrhea is an unfortunate long-term consequence of chemotherapy used to treat cancer and autoimmune disorders such as systemic lupus erythematosus.[62-67] Other agents may affect microvascular stability or hormone production/release, causing drug-induced amenorrhea/oligomenorrhea (Table 34-1).[55-61]

EPIDEMIOLOGY

A persistent menstruation disorder is often the primary reason for a woman to seek medical attention. Both amenorrhea and oligomenorrhea are often symptoms of more complex endocrine, gynecologic, or metabolic disorders.[70] *Intermenstrual bleeding*, often described as *breakthrough bleeding*, is bleeding that occurs between regular menses and is usually associated with nonadherence with oral contraceptives or inadequate doses of oral contraceptives based on endogenous, baseline hormone concentrations that may vary between individuals.[70,71]

Antiepileptic drugs such as phenytoin, valproic acid, and carbamazepine alter various aspects of endocrine function, although endocrine dysfunction has itself been associated with epilepsy. From 12% to 59% of women receiving antiepileptic drugs experience amenorrhea/oligomenorrhea.[75] More than 60% of women receiving cytotoxic chemotherapy have experienced one or more symptoms of ovarian failure.[64] The incidence of amenorrhea/oligomenorrhea associated with other drugs is unknown, as the evidence is published primarily in the form of case reports.

MECHANISMS

Drugs can affect uterine function through direct effects on the endometrium, such as causing microvascular instability that leads to breakthrough bleeding.[71] Antineoplastic drugs exert a direct toxic effect on oocytes, decreasing follicular formation and halting ovulation, leading to amenorrhea.[56] Drugs can also indirectly inhibit the negative feedback loop of the hypothalamic–pituitary pathway via modulation of serum hormone concentrations. This leads to decreased FSH and LH release, resulting in decreased ovarian function and induction of amenorrhea/oligomenorrhea.[68-74]

Antiepileptic drugs such as phenytoin and carbamazepine have been reported to increase serum concentrations of hormone-binding globulin, resulting in increased binding of estradiol and thus less free/active circulating estradiol resulting in amenorrhea/oligomenorrhea.[75-79] The mechanism of valproic acid–induced amenorrhea is not well understood, but it is thought to be related to weight gain, elevated serum insulin concentrations, and decreased serum concentrations of insulin-like growth factor I, leading to decreased ovarian androgen synthesis.[75,79-81] Mechanisms of drug-induced amenorrhea and oligomenorrhea are described in Table 34-2.[55-61]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Patients with drug-induced amenorrhea/oligomenorrhea often will present with either no menses or irregular bleeding. These symptoms may occur at any time after therapy with the causative drug is initiated. Amenorrhea is a common presenting symptom of ovarian failure and is typically not the only symptom that patients may experience related to the hormonal imbalances. Other symptoms include mood swings, irritability, vaginal dryness, dyspareunia, decreased cervical mucus, and thinning of the vaginal mucosa (Table 34-3).[53]

Drug-induced amenorrhea/oligomenorrhea must be differentiated from other causes, including endocrine disorders, metabolic disorders, anorexia nervosa, pituitary or hypothalamus tumors, or excessive psychological or emotional stress (Table 34-4).[60]

RISK FACTORS

Women who have advanced in age to the perimenopausal stage are more susceptible to drug-induced amenorrhea/oligomenorrhea.[55] The probability of permanent chemotherapy-induced amenorrhea or menopause increases proportionally with advancing age.[55] Poor nutritional status caused by crash diets or anorexia nervosa can also influence the susceptibility to drug-induced amenorrhea/oligomenorrhea.[60] Physiologic stress such as excessive exercise (e.g., marathon training programs) and psychological stress (e.g., anxiety, work/school/family pressure) also increases the risk of drug-induced amenorrhea/oligomenorrhea (Table 34-5).[60]

MORBIDITY AND MORTALITY

Drug-induced amenorrhea/oligomenorrhea is not associated with increased mortality but can significantly impact quality of life. Drug-induced amenorrhea/oligomenorrhea may interfere with the ability to plan conception as well as to conceive and can be associated with numerous other undesirable symptoms that interfere with daily activities and relationships, including vaginal dryness, moodiness, and painful intercourse.[53,60,70] Drug-induced amenorrhea/oligomenorrhea may disguise underlying gynecologic and endocrine conditions requiring medical evaluation, including polycystic ovarian syndrome and hypothyroidism.[60,82]

PREVENTION

No specific studies have addressed the prevention of drug-induced amenorrhea/oligomenorrhea. Oral contraceptives and gonadotropin-releasing hormone (GnRH)–agonists inhibit ovarian function, primarily ovulation, which may decrease susceptibility to the gonadotoxic effects of chemotherapy.[60,61,64,83] The use of oral contraceptives or GnRH-agonists during courses of cytotoxic chemotherapy has demonstrated some benefit in the prevention of drug-induced ovarian failure/amenorrhea; this preventive strategy is successful primarily in younger patients.[60,61,80] Use of GnRH agonists has shown limited benefit for the prevention of chemotherapy-induced amenorrhea/ovarian failure in perimenopausal women.[60,61] Maintenance of a well-balanced diet with regular exercise may help reduce the risk of developing drug-induced amenorrhea/oligomenorrhea (Table 34-6).

MANAGEMENT

Treatment options for drug-induced amenorrhea/oligomenorrhea vary depending on the causative agent. Drug-induced amenorrhea/oligomenorrhea associated with the use of progesterone implants can be reversed, if the patient desires, by discontinuing the implant and selecting an alternative contraceptive agent, such as oral contraceptives, or using alternative modes of contraception such as barrier methods.[66,72] Breakthrough bleeding can be decreased by encouraging better patient adherence or use/changing hormone concentration of the oral contraceptive product (OCP). If breakthrough bleeding is occurring early in the menstrual cycle, an OCP with higher estrogen content (up to 50-mcg ethinyl estradiol) may help or, if later in the cycle, an OCP with higher progesterone content may help.[60]

Once the causative agent is discontinued or doses modified, drug-induced amenorrhea/oligomenorrhea usually resolves within 4–6 weeks (Table 34-7). GnRH agonists (e.g., leuprolide 3.75 mg intramuscularly once monthly) may promote the reversal of chemotherapy-induced amenorrhea/ovarian failure in some younger patients.[61,64,80] However, because chemotherapy-induced amenorrhea (ovarian failure) is often permanent, in most cases it is advisable to discuss alternative options to compensate for future infertility, such as cryopreservation of embryos, unfertilized ova, or ovary cortex tissue (contains primordial follicles) before chemotherapy administration.[60]

INFORMATION FOR PATIENTS

Patients receiving drugs that may induce amenorrhea or oligomenorrhea should be counseled that amenorrhea is the absence of menstrual bleeding and oligomenorrhea is the presence of infrequent/irregular menstrual cycles, and that if either occurs a healthcare provider needs to evaluate the patient. Patients who will be receiving cancer chemotherapy agents that may cause drug-induced amenorrhea and ovarian failure should be informed of the potential for occurrence of this drug-induced disease. Healthcare providers should discuss the potential impact on fertility and options for future childbearing with the patient before chemotherapy administration.[64,65,80,81]

MENORRHAGIA AND MENOMETRORRHAGIA

Menorrhagia, also described as heavy menstrual bleeding, is prolonged menses or excessive bleeding that occurs at regular intervals. *Menometrorrhagia*, also described as intermenstrual bleeding, is prolonged menses or excessive bleeding that occurs at irregular intervals.

CAUSATIVE AGENTS

Drug-induced menorrhagia has been reported with the use of selective serotonin reuptake inhibitors (SSRIs), hormones (estrogen and progesterone), intrauterine contraceptive devices (IUDs), and prostaglandins (Table 34-1).[81-88] Drug-induced menometrorrhagia has been found to be associated with the oral and topical use of ginseng and the investigational agent recombinant human relaxin, which is a disease-modifying agent that has demonstrated benefit in the treatment of scleroderma.[87,88]

EPIDEMIOLOGY

The incidences of drug-induced menorrhagia or menometrorrhagia have not been clearly determined. There are few case reports or reviews that describe the risk.[70,89-91] In one large study evaluating the associated risk of bleeding caused by SSRIs, the incidence of drug-induced menorrhagia or menometrorrhagia was <1%.[92] As many as 50% of women receiving maintenance therapy with methadone experience drug-induced menorrhagia or menometrorrhagia.[70] Historically, menorrhagia and menometrorrhagia are among the most common reasons for discontinuing IUD use, as the incidence of these diseases increases by 70–100% in association with the insertion of copper-containing IUDs. However, the incidence of menorrhagia or menometrorrhagia is only approximately 2–4% in patients using the levonorgestrel-releasing IUD.[72]

MECHANISMS

Serotonin receptors, those specific for 5-hydroxytryptamine$_{2a}$, are expressed on platelets. Serotonin is released during platelet activation and binds to these receptors, contributing to platelet aggregation and thrombus formation. Administration of SSRIs results in a relative decrease in clotting function, resulting in potential episodes of drug-induced menorrhagia.[81,82] The cause of increased blood loss in association with IUDs is unclear. When exposed to IUDs, concentrations of hydrogen peroxide and prostaglandins in uterine tissue increase, but whether or not this is related to menorrhagia is unclear.[83,89]

The mechanism of ginseng-induced menometrorrhagia is not known. Relaxin-induced menometrorrhagia results from the induction of vascular endothelial growth factor receptor expression in the endometrial cell.[85] Table 34-2 describes the mechanisms for drug-induced menorrhagia and menometrorrhagia.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Patients with drug-induced menorrhagia present with a chief symptom of heavy or prolonged menstrual cycles that may occur at any time after the initiation of treatment with the culprit agent (Table 34-3). Drug-induced menorrhagia or menometrorrhagia may lead to the development of anemia and fatigue.

Drug-induced menorrhagia or menometrorrhagia must be distinguished from nondrug-induced causes, including common uterine complications such as fibroids or polyps or endometriosis.[93-97] Patients with menorrhagia or menometrorrhagia should undergo a complete physical exam and an endometrial biopsy to determine the primary cause. Endometrial biopsy can detect abnormal hyperplasia or cancer but cannot differentiate between a drug-induced and a nondrug-induced cause (Table 34-4).

RISK FACTORS

There are no known risk factors for drug-induced menorrhagia or menometrorrhagia.

MORBIDITY AND MORTALITY

If drug-induced menorrhagia or menometrorrhagia is left untreated, it may lead to more significant health complications, including anemia, thrombocytopenia, shortness of breath, altered nutritional status, and episodes of syncope. The majority of these symptoms can be directly associated with blood loss. Diminished nutritional status is an indirect result of fatigue associated with anemia that leads to decreased appetite and weight loss.

PREVENTION

Oral contraceptive therapy may be instituted prophylactically in patients undergoing treatment with SSRIs to prevent the development of menorrhagia.[86,96]

Oral contraceptives may also help prevent recurrent episodes of bleeding in patients with a history of menorrhagia/menometrorrhagia.[98] Avoidance of other platelet-inhibiting agents such as aspirin may decrease the risk of drug-induced menorrhagia or menometrorrhagia (Table 34-6).[97,99]

MANAGEMENT

Drug-induced menorrhagia is usually effectively treated with combination oral contraceptive therapy. Product selection is generally based on patient and prescriber preference.[86,96,99] Patients who have had menorrhagia for an extended time may also require iron-replacement therapy until the hemoglobin concentration returns to normal. In patients with IUDs, therapy with the antioxidant vitamin E (100 international units once every other day for 14 days) has been successful in attenuating menorrhagia.[83] Drug-induced menometrorrhagia can be effectively treated with GnRH agonists such as leuprolide (3.75 mg intramuscularly once monthly) or goserelin (3.6 mg intramuscularly once monthly).[94,96] When a patient is experiencing drug-induced menorrhagia or menometrorrhagia, the risks and benefits of discontinuation of the causative agent should be weighed. If the causative agent is discontinued, it may take up to 3 months for symptoms to resolve completely.

INFORMATION FOR PATIENTS

Patients receiving drugs that may cause menorrhagia or menometrorrhagia should be counseled that heavy or prolonged menstrual cycles (at regular or irregular intervals) may occur and that this should prompt them to seek medical attention.

DYSMENORRHEA

CAUSATIVE AGENTS

Drug-induced dysmenorrhea is associated with known uterine stimulants such as oxytocin and known vasoconstrictors such as vasopressin (antidiuretic hormone) (Table 34-1).[102] Estrogen and progesterone are also believed to be associated with some cases of drug-induced dysmenorrhea.[100,101]

EPIDEMIOLOGY

Dysmenorrhea is one of the most common gynecologic symptoms of menstruating women, with an incidence ranging from 3% to 90%.[101] The incidence and magnitude of drug-induced dysmenorrhea is unknown. It is possible that dysmenorrhea has been overlooked as a drug-induced condition, and occurrences therefore may be underreported.

MECHANISMS

Dysmenorrhea occurs often with normal ovulation because release of arachidonic acid promotes the release and elevated serum concentrations of prostaglandin-2α that mediates vasoconstriction and leukotrienes initiating the inflammation that produces cramps, bloating, and abdominal discomfort.[102] Drug-induced dysmenorrhea associated with the administration of the combination of oxytocin and vasopressin occurs as a result of vasopressin-related antidiuretic effects that alter the uterine contractions stimulated by oxytocin into a dysrhythmic and painful pattern (Table 34-2).[101]

The mechanism of estrogen- and progesterone-induced dysmenorrhea is not well understood. It has been suggested that the rapid fluctuations in serum hormone concentrations, primarily progesterone withdrawal, activates the inflammation cascade, causing pelvic congestion (swelling) and contributing to the development of dysmenorrhea (Table 34-2).[103,104]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Dysmenorrhea is a pelvic pain that occurs in relationship to menses. It is associated with a variety of symptoms, including nausea, vomiting, diarrhea, bloating, headache, backache, syncope, dizziness, breast tenderness, abdominal cramping, mood changes, nervousness, and fatigue (Table 34-3). Symptoms typically present within 24–48 hours before menstruation begins and usually continue for 48–72 hours after menstruation commences.[101] Drug-induced dysmenorrhea must be distinguished from other causes of dysmenorrhea. Pelvic pain with menses can be a natural physiologic occurrence in association with ovulation or premenstrual syndrome or may have other primary or secondary causes, including adverse effects of drugs (Table 34-4).[101,102]

RISK FACTORS

Diets high in omega-6 fatty acids, including most Western diets, increase the release of arachidonic acid after progesterone withdrawal and may result in inflammation and cramping (Table 34-5).[101] Early menarche and heavier menstrual blood flow are both associated with an increased risk of drug-induced dysmenorrhea.[103,104] Individuals who have more than one first-degree relative with dysmenorrhea have a higher risk of drug-induced dysmenorrhea.[101,105]

MORBIDITY AND MORTALITY

Dysmenorrhea is one of the most common gynecologic symptoms associated with repeated absenteeism from school or work.[102] Although dysmenorrhea has significant impact on quality of life, it is not associated with mortality.

PREVENTION

Drug-induced dysmenorrhea can be prevented by avoiding the use of uterine-stimulating drugs in women predisposed to the disorder. In women with a history of dysmenorrhea, prophylactic use of NSAIDs (e.g., ibuprofen 400 mg orally every 6 hours or 800 mg orally every 8 hours or cyclooxygenase [COX]-2 inhibitors such as celecoxib 200 mg orally once daily) often is effective to decrease and limit the symptoms of drug-induced dysmenorrhea (Table 34-6).[102,103,106]

MANAGEMENT

Management of drug-induced dysmenorrhea should be individualized to the patient's pain threshold, contraception goals, and overall health status. Hot or cold compresses may help provide some temporary relief. NSAIDs (e.g., ibuprofen 400 mg orally every 6 hours or 800 mg orally every 8 hours) or COX-2 inhibitors (e.g., celecoxib 200 mg orally once daily) are effective for alleviation of pain, and therapy should be continued until the end of menses (Table 34-7).[102,105] In patients with lower pain thresholds, short-term use of combination opioid products might be considered.[103,105] Acetaminophen alone is not as effective as NSAIDs in controlling the inflammation and symptoms associated with dysmenorrhea.[106]

INFORMATION FOR PATIENTS

Patients taking medications that may cause dysmenorrhea should be informed of the possibility and should be instructed to take anti-inflammatory medications at the first symptoms. Prompt treatment will help control the pain and can prevent the development or more significant discomfort. Patients should take NSAIDs with food to avoid development of gastrointestinal distress. Patients with sulfa allergies should avoid the use of COX-2 inhibitors.

SEXUAL DYSFUNCTION

Human sexual response can be classified into five phases: desire, excitement, plateau, orgasm, and resolution.[107] Sexual desire is an innate component of human social well-being. Any impairment or abnormality in the human sexual response is defined as sexual dysfunction.

CAUSATIVE AGENTS

Drug-induced sexual dysfunction often contributes to patient nonadherence to important medications, including antihypertensives, antidepressants, antipsychotics, sedatives, antiretroviral agents, androgen antagonists, and narcotics.[107-111] Alcohol may also interfere with sexual function. Sexual dysfunction can be classified into two categories: disorders of libido and disorders of excitement and orgasm. Disorders of libido are generally mediated by neuronal factors, whereas disorders of excitement and orgasm generally involve the genital organs. Drugs associated with sexual dysfunction in women are listed in Table 34-1.[101-112,117-122]

EPIDEMIOLOGY

Drug-induced sexual dysfunction in women is often underreported but is one of the contributing factors to nonadherence to prescribed pharmacotherapy and decreased quality of life.[111] It is difficult to distinguish drug-induced sexual dysfunction from the effects of specific diseases on sexual function. This is especially true with psychiatric disorders, where the disease itself has profound effects on social and sexual function.[112] Since the success of sildenafil and similar drugs for the treatment of erectile dysfunction, there has been increased attention to the incidence of drug-induced sexual dysfunction.[112] Antidepressants have been associated with decreased libido and sexual dysfunction, with an incidence in women ranging from 16.3% to 57%.[113-115] Antipsychotic agents such as haloperidol, risperidone, and thioridazine have been associated with a 28–93% incidence of drug-induced sexual dysfunction in women.[116-121] Antiretroviral agents are associated with an incidence of drug-induced sexual dysfunction of 40%.[110] The incidence of drug-induced sexual dysfunction associated with the use of antihypertensive agents in women is approximately 11%.[122]

MECHANISMS

Drug-induced sexual dysfunction is often associated with agents that affect the autonomic and central nervous systems and with agents that elevate serum prolactin concentrations (Table 34-2). For example, antipsychotic agents are known to elevate serum prolactin concentrations via inhibition of dopamine-2 receptors that are responsible for blocking prolactin secretion.[123-125] The mechanism by which prolactin diminishes libido and causes orgasm disturbances is not well understood.[110,111,116,122,125] Elevated serum prolactin concentrations have been associated with decreasing serum testosterone concentrations, which may contribute to diminished libido.[126]

Drug-induced sexual dysfunction, primarily loss of libido and orgasm dysfunction, has been associated with all classes of antidepressant agents.[112,125,127] Although the mechanism involved is not well understood, antidepressants may cause sexual dysfunction by altering central serotonergic activity and indirectly influencing adrenergic activity. Alterations in central serotonergic activity may disrupt hypothalamic–pituitary axis regulation of hormone release, including the release of testosterone. Indirect effects on adrenergic activity may contribute to direct effects on gonads, leading to decreases in muscle tension, vaginal lubrication, or both.

Antihypertensive agents are more often associated with erectile dysfunction and diminished libido in men. However, these drugs may also decrease libido in women via antiandrogenic and antidopaminergic activity. The mechanism by which antiretroviral agents induce sexual dysfunction is not well understood. It has been shown that serum hormone concentrations are not altered in patients receiving antiretroviral agents, suggesting that the mechanism of antiretroviral-induced sexual dysfunction involves a yet to be determined nonhormone-related pathway.[110]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Identifying individuals who have drug-induced sexual dysfunction can be difficult because patients are often embarrassed and hesitant to report sexual complications to the healthcare team.[128] Healthcare providers should specifically ask questions regarding sexual activity and relations and should volunteer information to dispel misconceptions that patients may have about sexuality to alleviate fear, guilt, or frustration regarding sexual dysfunction.

Once comfortable, patients may begin to volunteer information regarding symptoms they are experiencing. These may include vaginismus, dyspareunia, or loss of libido or orgasm dysfunction (Table 34-3). Dyspareunia can often be attributed to physical disorders of the vagina, such as decreased lubrication, infections, or local irritation. Patients with loss of libido or orgasm dysfunction often present with other psychological symptoms, including depression, fatigue, anxiety, anger, or fear (Table 34-4). Again, extensive counseling and discussion is necessary to sort through the vague symptoms. A close evaluation of the medication history is necessary to determine whether sexual dysfunction can be attributed to a drug. Drug-induced sexual dysfunction usually occurs within 2 weeks of initiating therapy with the culprit agent, although SSRI-induced sexual dysfunction may take longer to manifest.

RISK FACTORS

Specific disease-related factors may increase the risk of drug-induced sexual dysfunction. These include endocrine disorders associated with hormone imbalances such as hypogonadism or hypothyroidism; neurologic/psychiatric impairments such as schizophrenia or depression; surgery such as hysterectomy, oophorectomy, or vulvovaginal resections; or pelvic irradiation that directly alters ovarian function or the structure or function of the vagina.[129] Anxiety, stress, depression, or substance abuse may compound the patient's psychological ability to tolerate and discuss symptoms associated with sexual dysfunction (Table 34-5).

Drug-induced sexual dysfunction is not always dose-related, but in some cases, especially those caused by antihypertensive agents or SSRIs, using lower doses or instituting "drug holidays" may help minimize symptoms.[112,122] Of course, the risk versus benefit would need to be part of this decision process before implementing a drug holiday or using lower doses.

MORBIDITY AND MORTALITY

The physical complications of drug-induced sexual dysfunction are not life-threatening. However, the psychological stress generated from these complications can significantly impact mental health (depression, anxiety, disposition) and quality of life and have negative impact on relationships with partners, family, and friends.

PREVENTION

Education is the most important component of prevention and may help lead to acceptance and improve the ability of the patient to communicate her concerns regarding sexual dysfunction. Counseling should include education regarding the potential for sexual complications associated with prescribed therapy and possible treatment options for symptom management. The risk of drug-induced sexual dysfunction should be weighed against the prescribed drug's potential therapeutic benefit and the availability of alternative treatment options. Avoidance of agents known to be associated with sexual dysfunction is recommended if and when acceptable alternative agents for treatment are available (Table 34-6).

MANAGEMENT

The first step in the management of drug-induced sexual dysfunction is completion of a thorough physical examination to determine any possible physical causes that could be contributing to symptoms. The patient's medication history should be closely evaluated to identify drugs that may be causing sexual dysfunction. Once a drug is identified as the likely source of sexual complications, alternative medical treatment options should be considered. It is sometimes reasonable to substitute therapy with other agents within the same class to determine whether symptoms improve. Although symptoms generally improve within 2 weeks after discontinuation of the causative agent, in some cases sexual function may not completely return to normal without additional interventions to treat the sexual dysfunction. This is often the case with sexual dysfunction associated with antipsychotic agents, where treatment of the drug-induced disease may be confounded by the underlying psychiatric disorder.[125]

Topical estrogen (estradiol 0.05–0.1 mg vaginal ring inserted once every 3 months, or estradiol 0.01% cream vaginally 2–4 g once daily for 2 weeks followed by once-weekly maintenance) may help improve arousal dysfunction by increasing vaginal secretions and engorgement.[128] Other pharmacotherapy to increase libido could include phosphodiesterase-5 inhibitors such as sildenafil citrate (50 mg orally 1 hour before sexual activity). In addition, vaginal lubricants and moisturizers may be used to relieve vaginal dryness and improve genital arousal (Table 34-7).[128] Mechanical stimulatory devices, such as vibrators, that increase blood flow to the vaginal muscle can be used in conjunction with pharmacologic interventions to optimize relief of symptoms.[128]

When treating a patient with drug-induced sexual dysfunction, it is extremely important to be sensitive and supportive. Psychological support and assurance can be extremely effective in alleviating the stress and anxiety experienced by patients with drug-induced sexual dysfunction.[129]

INFORMATION FOR PATIENTS

Sexual function is an important component of adult relationships. Patients who are taking antipsychotic agents, antidepressants, antihypertensive agents, or other drugs associated with sexual dysfunction should be counseled regarding the potential for occurrence of this drug-induced disease and should be instructed to discuss symptoms such as painful intercourse, vaginal dryness, lack of or decreased orgasm, or diminished libido with their healthcare provider.

INFERTILITY IN WOMEN

CAUSATIVE AGENTS

Drug-induced infertility is a tragic yet predictable outcome associated with treatment with cytotoxic chemotherapy agents. Although there is potential for drug-induced infertility after treatment with any cytotoxic agent, the most common classes of agents that cause infertility include the alkylating agents, platinum analogues, antitumor antibiotics, antimetabolites, and vinca alkaloids (Table 34-

1).[130-144] Even patients who may resume normal menses after completion of cytotoxic chemotherapy may not have a viable ovarian follicular reserve.[132] Whereas cytotoxic agents are associated with permanent infertility, caffeine is associated with a reversible or transient infertility.[133-137] Caffeine is found in many beverages and is an additive in both prescription and nonprescription medications. In addition to infertility, caffeine has also been associated with a dose-related increased risk of miscarriage in the first trimester.[138] Many antiepileptic drugs have been associated with endocrine dysfunction and drug-induced infertility that is reversible once medication is stopped.[78-80,88,139-144]

EPIDEMIOLOGY

Women with cancer are most often afflicted with drug-induced infertility after completion of a cytotoxic chemotherapy regimen. However, lower doses of these same cytotoxic agents are used in treatment of systemic lupus erythematosus or other autoimmune disorders and can cause drug-induced infertility in these situations as well. In addition, the very prevalent use of caffeine today could put many women at risk for reversible drug-induced infertility.

MECHANISMS

Antineoplastic drugs have a direct toxic effect on oocytes, decreasing follicular formation and halting ovulation resulting in permanent drug-induced infertility.[56] This also leads to decreased FSH and LH release, resulting in decreased ovarian function and induction of infertility.[68-74] Antiepileptic drugs have also been reported to increase the serum concentration of hormone-binding globulin, resulting in decreased binding of estradiol, which can result in drug-induced infertility.[75-79] The mechanism of drug-induced infertility is not as well understood for caffeine (Table 34-2).

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Drug-induced infertility associated with cytotoxic agents is fairly easy to recognize because most of these drugs cause infertility. Conversely, the diagnosis of reversible drug-induced infertility associated with caffeine is more difficult to establish and requires a detailed medication and diet history. The obvious and primary symptoms of drug-induced infertility include inability to conceive and/or frequent miscarriages (Table 34-3). Patients may also have cessation of menses or irregular menses. Underlying or contributing endocrine or metabolic conditions should be ruled out as well as possible early menopause. Conditions to consider in the differential diagnosis of drug-induced infertility are presented in Table 34-4.

RISK FACTORS

The probability of permanent drug-induced infertility after chemotherapy increases proportionally with advancing age.[144,145] In patients with autoimmune disorders, there are specific disease-related factors that may increase the risk of drug-induced infertility, including the presence of antiovarian antibodies, polyglandular insufficiency, and viral infections.[146-148] Epilepsy also has been associated with an increased risk for endocrine disorders resulting in infertility (Table 34-5).[149]

MORBIDITY AND MORTALITY

As with drug-induced sexual dysfunction, the physical complications of drug-induced infertility are not life-threatening. However, finite and predictable infertility can be associated with significant psychological stress reflected in a diminished mental health (i.e., depression, reduced self-esteem), a decreased quality of life, and a negative impact on relationships with partners, family, and friends.

PREVENTION

Instructing patients to reduce or to eliminate the frequent consumption of caffeine-containing beverages and medications from their diet can prevent caffeine-induced infertility. Patients will find that fertility is regained within months after the discontinuation of caffeine consumption. Efforts to prevent drug-induced infertility associated with other agents may not be as successful. Some studies have suggested the use of oral contraceptives during chemotherapy in younger patients may help prevent permanent drug-induced infertility by temporarily halting ovulation, which may protect oocytes from exposure to offending chemotherapy.[144] Another pharmacologic option that has been proposed, although still controversial, is the prophylactic use of GnRH agonists to also temporarily halt ovulation, which may protect oocytes from exposure to offending chemotherapy to prevent permanent drug-induced infertility (Table 34-6).[61,150,151]

MANAGEMENT

Management strategies for drug-induced infertility are listed in Table 34-7. Prior to receiving cytotoxic chemotherapy, patients need to be made aware of the high risk and likelihood of drug-induced infertility, which in most cases will be permanent. These patients need to consider multiple options for cryopreservation of eggs or embryos to preserve fertility options once treatment is completed. Factors that can influence this decision include time restraints (how quickly treatment needs to be initiated), the type of cancer or disease being treated (specifically if estrogen-sensitive), whether or not the patient has a partner, desire to have (more) children, and the patient's age. For those with a partner and enough time before cytotoxic therapy begins, cryopreservation of embryos is preferred and has the highest success rate.[152] Other cryopreservation options include freezing of oocytes, ovarian cortex, or follicles.[152,153] Although these options do not require a partner and can be accomplished in less time than cryopreservation of embryos, the potential of achieving viable pregnancies is less than with cryopreservation of embryos.

For patients receiving antiepileptic drugs, infertility is often, but not always, reversible once the culprit agent is removed and endocrine function is allowed to normalize. Unfortunately, the option to discontinue medications is generally available only for patients whose seizure disorder can be managed effectively by an alternative, newer antiepileptic agent.[149]

INFORMATION FOR PATIENTS

Infertility is a highly sensitive and emotional topic for most women and couples. In some cases, fertility is the essence of a women's identity. Patients about to receive cytotoxic chemotherapy need to be educated regarding the multiple methods available to preserve fertility options after completion of treatment. Once treatment is completed and residual treatment-related toxicities have resolved, patients should be encouraged to exercise fertility options at that time to avoid additional complications with pregnancy. In patients receiving antiepileptic drugs, the potential for infertility should be discussed prospectively and alternative agents should be considered. Patients should understand that there is no guarantee that fertility will return after removal of the offending agent. Finally, patients with drug-induced infertility associated with caffeine intake should be counseled on the benefits of the short-term cessation of all caffeine products and caffeine-containing medications. Patients should be reminded that caffeine withdrawal side effects are temporary and resolve quickly and that the potential benefit of regaining fertility and the prevention of miscarriages outweighs any short-term discomfort.

Upper Gastrointestinal Ulceration

Dianne W. May, Micaela Carroll, and J. Russell May

The upper gastrointestinal (GI) tract consists of the mouth, pharynx, esophagus, stomach, and duodenum. The ligament of Treitz, or the suspensory muscle of the duodenum, is found at the duodenojejunal flexure and is typically used as a landmark to differentiate between the upper and lower GI tract.[1] Any injury that occurs before the ligament of Treitz would be considered an upper GI event. Drug-induced ulcerations of the upper GI tract can occur anywhere in this region before the jejunum, but the esophagus and stomach are primary targets. Patients may present with signs and symptoms that range from benign lesions with no sequelae to serious complications including GI bleeding, strictures, perforation, and obstruction. Distinguishing characteristics of drug-induced mucosal damage of the upper GI tract are typically evident on endoscopy. Understanding the mechanisms and risk factors for drug-induced upper GI ulceration can help healthcare providers minimize and manage the complications that may occur.

CAUSATIVE AGENTS

Medications that have been reported to cause upper GI ulceration are listed in **Table 35-1**.[2-19] Overall, nonsteroidal anti-inflammatory drugs (NSAIDs), including aspirin, are the most common causative agents. The risk of gastrointestinal toxicity with NSAIDs is not specific to route used. Gastrointestinal toxicity is seen with the oral route as well as the intravenous route.[20] Other medications that are commonly associated with upper GI ulceration include ferrous sulfate, quinidine, doxycycline, selective serotonin reuptake inhibitors (SSRIs), and corticosteroids (especially when used in combination with other medications that can cause ulceration).

The mucosa of the esophagus is particularly vulnerable to the direct mucosal injury that can occur with many medications. Over 70 medications have been associated with esophageal damage, including certain bisphosphonates (e.g., alendronate), potassium chloride (oral), aspirin, clindamycin, ferrous sulfate, quinidine, valproic acid (sustained-release), and tetracyclines.[2,10] Many β-lactams, including penicillin, ampicillin, amoxicillin, and cloxacillin have been implicated in causing pill-induced esophagitis. The gelatin capsule of many antibiotics is sticky and, therefore, makes the capsule prone to esophageal retention.[21] Esophageal perforation has been reported with sustained-release valproic acid, aspirin-caffeine products, and sustained-release ferrous sulfate.[2] Although anticoagulant and antiplatelet medications may increase the risk of bleeding, they are not generally considered major culprits in upper GI ulceration. The exception is dabigatran, a direct thrombin inhibitor, which has been associated with symptomatic esophagitis.[13]

Table 35-1 Agents Implicated in Drug-Induced Upper Gastrointestinal Ulceration

Drug	Incidence	Level of Evidence[a]
Ascorbic acid[2,3]	NK	C
Aspirin[4,5]	10–15%	A
Bisphosphonates (oral)[3,6,7,8]	0.2–0.4%	A
Ciprofloxacin,[9] clindamycin[10]	NK	C
Clopidogrel[11]	NK	B
Corticosteroids[6,12]	0.4%	B
Dabigatran[13,14]	NK	C
Erythromycin[6]	NK	C
Ferrous sulfate[2,3]	5%	B
Nonselective NSAIDs[15,16]	10–25%	A

Potassium chloride (oral)[2,3]	8–19%	A
Quinidine[2,3]	NK	C
Selective COX-2 NSAIDs[17]	5–8%	A
Selective serotonin reuptake inhibitors[18,19]	NK	B
Sulfasalazine[6]	NK	C
Tetracyclines[2,6]	NK	B
Valproic acid[2]	NK	C

COX = cyclooxygenase, NK = not known, NSAIDs = nonsteroidal anti-inflammatory drugs.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

EPIDEMIOLOGY

The true incidence of drug-induced upper GI ulceration is difficult to determine because of possible under-reporting or misdiagnosis. Many patients self-medicate, making it impossible to know actual exposure rates. In addition, some patients in whom ulceration develops have minimal sequelae or are asymptomatic. Dyspepsia, for example, is present in <50% of patients taking NSAIDs who present with life-threatening complications such as GI bleeding or perforation.[15] Additionally, event rates often change over time; recent data showed that rates of GI adverse events in women taking bisphosphonate therapy increased from 16.1%, to 25.6%, to 38.9% at 3, 6, and 12 months, respectively.[22] Another factor that complicates the collection and interpretation of incidence data is the use of differing definitions for the diagnosis of drug-induced upper GI ulceration that appear in published literature. Knowing the criteria that were used to define ulceration is important when attempting to compare study results.

Notwithstanding the difficulties described above, NSAIDs, which includes aspirin, appear to be the most common cause of upper GI ulceration.[16] Endoscopic surveys of patients receiving ≤325 mg aspirin daily reported gastroduodenal ulcers in 11% of patients.[23] More serious GI complications may also develop in patients receiving NSAIDs including bleeding, stricture formation, and perforation.[6,15] The incidence of hospitalization for NSAID-induced upper GI bleeding has been reported to be as high as 2.2% annually in patients with rheumatoid arthritis.[16]

The highest risk for upper GI ulceration in patients receiving NSAIDs appears to occur when these agents are used in combination with other medications also known to cause GI ulceration. When combined with even low doses of aspirin

(<325 mg/day), the risk of upper GI bleeding in patients receiving other NSAIDs may be increased as much as 12-fold. The presence of *Helicobacter pylori* (*H. pylori*) infection has also been shown to increase the risk of upper GI ulceration in those taking NSAIDs, including low-dose aspirin, and also in those taking thienopyridines. Peptic ulcers were identified on endoscopy in 10.7% of elderly patients on aspirin doses of 75–325 mg per day. Interestingly, eradicating *H. pylori* infection prior to starting low-dose aspirin was not associated with an increased risk of upper GI ulceration. With NSAIDs other than aspirin, the presence of *H. pylori* infection is an independent risk factor for NSAID-induced ulcers. Fortunately, eradicating *H. pylori* infection prior to initiating NSAID therapy decreases that risk by up to 57%. The benefit of eradicating *H. pylori* in chronic NSAID users is less clear.[24]

Although the incidence of drug-induced upper GI ulceration is relatively low in patients receiving corticosteroids and selective serotonin reuptake inhibitors alone, the combination of these drugs with an NSAID increases the risk for ulceration considerably. Patients taking a selective serotonin reuptake inhibitor concurrently with an NSAID had as much as a 3.6-fold increase in the risk of upper GI bleeding.[18] The incidence of ulceration appears to be least common with ibuprofen, especially at doses <1,200 mg/24 hours. Selective cyclooxygenase (COX)-2 NSAIDs also are associated with a lower incidence of drug-induced ulceration ranging from 5% to 8%.[25]

Although GI damage due to NSAIDs is most common at sites distal to the esophagus, they can cause esophageal damage as well. One review of medications associated with drug-induced esophageal injury showed NSAIDs to be responsible for 40% of cases. This was followed by tetracyclines (22%), potassium chloride (10%), and bisphosphonates (9%). Antimicrobials, quinidine, and ascorbic acid were responsible for the remainder of cases.[2] Dabigatran, a direct thrombin inhibitor that was approved in 2010, has also been implicated in several cases of symptomatic esophagitis.[13] With both dabigatran and rivaroxaban, another direct thrombin inhibitor, lower GI bleeding reported in clinical trials was more common than upper gastrointestinal bleeding.[26]

MECHANISMS

Various mechanisms are responsible for drug-induced upper GI ulceration, ranging from simple direct irritation of the GI lining to more complex interactions with mucosal cells and prostaglandin inhibition. Because ulceration can occur in the absence of direct contact with the GI tract, no route of administration can be considered completely safe with respect to this drug-induced disease. An understanding of mechanisms is important in preventing or minimizing adverse effects in patients at greatest risk. **Table 35-2** lists causative agents with their proposed mechanism(s). With some medications, more than one mechanism may be involved.[1-3,6,9-11,13,14,18,19]

Table 35-2 Mechanism(s) of Drug-Induced Upper Gastrointestinal Ulceration

Drug	Mechanism(s)
Aspirin[6]	COX inhibition, platelet effects, direct irritant
Bisphosphonates (oral)[2,6]	Direct irritant
Ciprofloxacin[9]	Chemical injury
Clindamycin[10]	Direct irritant
Clopidogrel[11]	Platelet effects
Corticosteroids[6]	Impair mucosal healing
Dabigatran[13,14]	Direct irritant
Erythromycin[6]	Direct irritant
Ferrous sulfate[1]	Direct irritant
Nonsteroidal anti-inflammatory drugs[6]	COX inhibition, platelet effects, direct irritant
Potassium chloride[3,6]	Direct irritant
Selective serotonin reuptake inhibitors[18,19]	Platelet effects
Tetracyclines[2,6]	Direct irritant

COX = cyclooxygenase.

NSAIDs have long been thought to cause upper GI ulceration through their inhibition of COX, a major enzyme needed for the synthesis of prostaglandins. Prostaglandins have a strong cytoprotective effect on the GI mucosa. They help maintain mucosal blood flow, increase secretion of mucus and bicarbonate, and augment epithelial defense against cytotoxic injury.[2] There are at least two subtypes of the COX enzyme, COX-1 and COX-2. COX-1 is the predominant subtype found in the stomach. NSAIDs that preferentially inhibit COX-2, therefore, might be expected to cause fewer adverse GI effects than those that inhibit COX-1. Indeed, when COX-1 inhibitors were directly compared with COX-2 inhibitors, patients experienced fewer minor GI problems with the COX-2 inhibitors.[17] Importantly, the risk of adverse GI effects is not completely eliminated with the use of these selective agents.[27] Celecoxib, for example, has been shown to increase the risk of GI toxicity compared with placebo.[28] Additionally, the long-term use of COX-2 inhibitors is limited because they have been associated with greater cardiovascular toxicity. Nonacetylated salicylates, such as salsalate, are weaker inhibitors of COX activity and therefore less damaging to the GI tract. NSAIDs also have a direct cytotoxic effect on GI mucosal cells that is independent of COX activity and can result in lesions and necrotic injury.[29]

As previously noted, the relationship between *H. pylori* positivity and the incidence of NSAID-induced GI ulceration appears to depend on when the NSAID therapy was started. New users of NSAIDs have been shown to have fewer ulcers and ulcer-associated complications if they are *H. pylori*-negative at time of initiation.[24,30] Whether the presence of one affects the mechanism of ulceration of the other is unknown. Clearly, *H. pylori* is an independent risk factor for NSAID-induced ulceration and ulcer bleeding.[24,31]

Corticosteroids have been implicated in GI ulceration, but the exact mechanism is unclear. These medications may impair mucosal healing through the reduction of epithelial regeneration.[32] Corticosteroids may pose a greater risk to the lower GI tract than to the upper GI tract.[2] Studies have failed to confirm the mechanism or quantify the actual risk.[12]

Pill-induced esophagitis, a localized ulcer of variable depth, can occur when capsules or tablets do not clear the esophagus in a timely manner. Gelatin capsules can become sticky and lodge in the esophagus if not taken with adequate water. In addition, tablets may be difficult to swallow or contain a caustic coating that causes direct mucosal irritation. The pH and concentration of the medication may also be contributing factors. Pill-induced esophagitis occurs commonly with oral bisphosphonates, such as alendronate. Even patients who strictly adhere to the recommended directions for use can experience esophagitis that is often exudative in nature and resolves with discontinuation of the medication. Oral potassium chloride may induce irritation in a localized area of the esophagus or stomach because of the high salt concentration. The slow-release, wax matrix formulations are more likely to cause damage than the microencapsulated forms. Liquid forms of potassium supplementation are much less likely to cause ulceration or other injury.[33] In most cases the esophageal injury is caused by the prolonged contact of medication, resulting in direct damage to the esophageal wall.[34] This also applies to dabigatran-induced esophagitis, with the tartaric acid contained within the capsules playing a role in causing tissue damage.[13]

A number of other mechanisms for drug-induced upper GI bleeding exist. Vascular shunting due to an increased osmotic load of sorbitol has led to ischemic necrosis in patients taking sodium polystyrene.[35] Clopidogrel may cause re-bleeding in patients with a history of bleeding because of its antiplatelet effect.[11] There is some evidence suggesting that selective serotonin reuptake inhibitors increase the risk of upper GI bleeding by possibly decreasing platelet serotonin and interfering with platelet aggregation.[19] This effect is potentiated when selective serotonin reuptake inhibitors are administered with NSAIDs, including low-dose aspirin.[18]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Patients with drug-induced GI ulceration may be asymptomatic or may present with life-threatening complications including bleeding, perforation, and strictures. The most common signs and symptoms of upper GI ulceration are listed in **Table 35-3**.[2,3] Heartburn, dyspepsia, cramps, and abdominal pain are common, but do not always correlate with ulceration. As previously noted, dyspepsia was reported by <50% of patients presenting with life-threatening bleeding due to NSAID use in one series.[15] Hematemesis and/or black, tarry stools may be signs of bleeding and should be carefully evaluated. Likewise, dysphagia, odynophagia, weight loss, or severe abdominal pain may be indicative of severe complications or other diseases (e.g., malignancy) and warrant careful evaluation.

Table 35-3 Signs and Symptoms Associated with Drug-Induced Upper Gastrointestinal Ulceration[2,3]

- Abdominal pain or tenderness
- Burning in the back or stomach
- Cramps
- Dyspepsia
- Heartburn
- Hematemesis
- Hematochezia
- Indigestion
- Nausea/vomiting
- Odynophagia

NSAIDs most commonly cause ulceration in the stomach. Ulceration of the small intestines is less common, and esophageal ulceration is the least common of the three sites. Of note, indomethacin, diclofenac, piroxicam, and aspirin have been shown to induce esophageal injury.[10] There appears to be a correlation between NSAID use and the development of esophagitis and esophageal strictures.[36] Although esophageal injury may not be as common with NSAIDs, when it occurs it can have serious consequences, including bleeding and stricture formation.

Patients with pill-induced esophagitis, as occurs with doxycycline or alendronate, may present with sudden, painful swallowing shortly after the offending agent is taken. It can also be described as a dull aching pain in the shoulder or chest.[3] Sequelae from this type of injury can include severe ulceration and strictures. Hemorrhage is rare, although patients may occasionally present with melena caused by esophageal bleeding.[37] Symptoms generally resolve within 7–10 days following discontinuation of the culprit drug.[3] Pill-induced esophagitis should be suspected whenever patients present with the above symptoms and especially in those without previous esophageal symptoms.

Patients with pill-induced esophageal injury due to oral solid dosage forms of potassium chloride tend to have progressive dysphagia with little pain.[10] The connection between drug and injury can be difficult to recognize, as symptoms may progress over months or even years. In many cases, strictures develop because of the chronic nature of injury. Healthcare providers should be alert for pill-induced esophagitis or gastritis in elderly patients who require oral potassium chloride supplements while being treated with diuretics for heart failure. Quinidine may cause production of an exudate and edema in the upper GI tract that must be distinguished from carcinoma.[10]

Lack of awareness of drug-induced GI injury can lead to persistent exposure to causative medications, resulting in severe complications. Many of the signs and symptoms associated with upper GI ulceration are also common with other diseases. It is important, therefore, to distinguish drug-induced upper GI ulceration from other ulcerative, erosive, or inflammatory conditions, as well as trauma, tumors, or other diseases. **Table 35-4** lists conditions that should be considered in the differential diagnosis of drug-induced upper GI ulceration.[2]

Table 35-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Upper Gastrointestinal Ulceration[2]

- Chest pain secondary to cardiovascular disease
- Crohn disease
- Esophageal stricture
- Gastric outlet obstruction
- Infectious cause of esophagitis (herpes, candida, HIV, cytomegalovirus)
- Malignancy
- Nasogastric intubation
- Peptic ulcer disease
- Perforation
- Reflux esophagitis
- Sclerotherapy
- Stevens–Johnson syndrome

HIV = human immunodeficiency virus.

Patients presenting with weight loss, recurrent emesis, and dyspepsia may have gastric outlet obstruction. Patients who present with chest pain or pain that radiates to the shoulder should be evaluated for cardiovascular causes. Dysphagia, odynophagia, and weight loss may be indicative of carcinoma and patients with these symptoms require careful evaluation.

It is difficult to distinguish pill-induced esophagitis from herpes esophagitis, because both may present radiographically as shallow ulcerations in the mid or distal esophagus. Differentiation can sometimes be made by determining the presence or absence of a temporal relationship between medication ingestion and the onset of symptoms. Patients with pill-induced esophagitis may experience an abrupt onset of odynophagia, dysphagia, or retrosternal burning pain within a few moments of taking the causative medication.[37] Patients with herpes-induced ulcers are usually immunocompromised, and their esophageal lesions tend to be more widely distributed than those in patients with pill-induced esophagitis.[10] Reflux esophagitis generally causes ulcers in the more distal segment of the esophagus.

There are several characteristic morphologic and pathophysiologic changes that can help differentiate drug-induced GI ulceration from other conditions.[35] Candidal esophagitis is characterized by its “shaggy” appearance due to plaque formation.[10] Crohn disease is usually distinguished by evidence of the disease in multiple parts of the GI tract, including the small and large bowel.[10] In pill-induced esophagitis, inflammatory markers are a common finding. Infiltration of macrophages, T lymphocytes, and intraepithelial mast cells and eosinophils can often be seen.[38] An exudative, ulcerative esophagitis may develop specifically in patients receiving alendronate. This exudate shows translucent crystalline material, with multinucleated giant cells seen in as many as 30% of cases, a process indicative of pill-induced esophagitis. In addition, alendronate-induced esophagitis may also manifest as strictures. Esophageal injury caused by dabigatran has been reported as both an exfoliative esophagitis and as esophageal ulceration.[14]

Iron-induced GI injury occurs most commonly in the esophagus, but the stomach may also be affected.[35] The injury manifests as a chemical burn with erosive injury and is characterized by brown-black crystalline material within the epithelium.[35] Less commonly, endoscopic examination can reveal impacted pill fragments, or remnants of drug coating.[37] Elderly patients are at increased risk for impacted pill fragments or drug coating remnants because of low saliva production. They also tend to consume more medications including bisphosphonates or NSAIDs.[37] Any patient who is in a recumbent position for extended periods is also at risk for iron-induced GI injury. Iron can also deposit in the stomach epithelium, causing damage.

Patients with uremia are very susceptible to vascular shunting because of the sorbitol osmotic load in sodium polystyrene. Basophilic crystalline material may be evident on morphologic evaluation. Ischemic necrosis has been reported. Most upper GI lesions due to sodium polystyrene are reversible and do not generally lead to serious sequelae.[35]

RISK FACTORS

Knowledge of the risk factors associated with GI bleeding caused by NSAIDs and those for bisphosphonate-induced esophageal damage provide excellent guidance when considering the risk associated with any of the medications described in this chapter. Risk factors for drug-induced upper GI ulceration are listed in **Table 35-5**.[2,6]

Factors that increase the risk for GI bleeding with aspirin specifically include dose, history of ulcer or upper GI bleeding, age >70 years, and concomitant use of other NSAIDs.[4] Other risk factors for GI bleeding with aspirin, even low-dose aspirin, are the concomitant use of corticosteroids or anticoagulants.[5]

A history of GI complications is the most important predictor of NSAID-induced GI toxicity.[39,40] Other risk factors include a history of uncomplicated peptic ulcer; age >75 years; concomitant use of corticosteroids, warfarin, or other NSAID, including aspirin; the dose of NSAID; a history of dyspepsia; and the disease being treated (e.g., due to the side effect profile of the medications used for treatment, patients with rheumatoid arthritis have higher prevalence of GI events than those treated for osteoarthritis).[39] The duration of NSAID use may also be an important factor in the development of GI toxicity. Short-term use (<1 week) in healthy patients is unlikely to be problematic; however, longer-term use is associated with increased GI toxicity. GI complications are most common within the first 3 months of the initiation of NSAID therapy.

Table 35-5 Risk Factors for Drug-Induced Upper Gastrointestinal Ulceration[2,6]

- Concomitant anticoagulation
- Concomitant corticosteroid use
- Concomitant use of two NSAIDs (including low-dose aspirin)
- *Helicobacter pylori* infection
- High NSAID dose
- History of gastrointestinal bleeding
- History of ulceration
- Increasing age
- Prolonged NSAID use
- Specific risks for pill-induced esophagitis:
  - Decreased saliva production
  - Fasting
  - Inadequate fluid intake
  - Returning to a supine position too soon after medication administration
  - Swallowing abnormalities (e.g., stroke, dysmotility, anatomic abnormalities)

NSAID = nonsteroidal anti-inflammatory drug.

Because COX-1 produces prostaglandins that are known to protect the GI mucosa, it is thought that NSAIDs with greater COX-1 inhibitory activity would present a greater risk of GI toxicity. This idea is supported by evidence that ketorolac, the NSAID with the greatest COX-1 inhibitory effects, produces the highest risk for GI bleeding of all the medications in this class.[41,42] COX-2 inhibiting agents (e.g., celecoxib) have a minimal effect on COX-1 and theoretically present a lower risk of GI bleeding. However, no NSAID is completely free of ulceration risks and associated complications. Most of the factors that raise the risk for GI complications in patients taking NSAIDs also increase the likelihood of GI complications in non-NSAID-treated patients.[25] As a result, patients may be at continued risk for GI complications even after switching to alternative medications. In addition, the incidence of cardiovascular toxicities has been shown to be higher with COX-2 inhibitors, so proper patient selection following evaluation of the risks and benefits is extremely important.

Patients who have undergone renal transplantation have multiple risk factors for GI ulceration, including the stress of surgery, use of NSAIDs and corticosteroids, and increased gastric acid secretion during dialysis postrenal transplantation.[43] Also contributing is the possible impairment of native GI cytoprotection due to azathioprine or mycophenolate-induced slowing of intestinal cell turnover. Ulcers can be asymptomatic with the symptoms masked by the use of corticosteroids. Risk factors for bleeding following transplantation include NSAID use for at least 1 week post-transplantation, high-dose intravenous corticosteroids used for acute rejection, and cyclosporine use.[43]

Patients with a history of GI bleeding may also be at increased risk of rebleeding when taking clopidogrel.[11] Nine of 70 such patients (14%) had significant GI bleeding after a median follow-up of 1 year. All except one lesion was identical to the previous lesion, suggesting that clopidogrel causes rebleeding only in patients with underlying mucosal defects or scarring. Pre-existing mucosal breaks, caused by esophagitis or peptic ulcers, can be aggravated by the antiplatelet effects of thienopyridines, promoting bleeding.[44] Healthcare providers should be alert to the fact that patients with a history of aspirin-induced GI bleeding are at high risk for the development of the same outcome with clopidogrel, which has been reported to have a favorable GI safety profile as compared with aspirin, although patients who were studied received only 325 mg doses of nonbuffered and nonenteric-coated aspirin. In addition, healthcare providers were permitted to exclude any patient they defined as aspirin-intolerant.[45]

Patients at risk for pill-induced esophagitis are those who do not take enough fluids with their medications, those with swallowing abnormalities due to stroke or esophageal dysmotility, and those with anatomic abnormalities such as strictures.[3] Other risk factors include fasting, decreased production of saliva, age >70 years, and polypharmacy.[10] Patients with left atrial enlargement are predisposed because the left atrium can compress the esophagus.[46] In most case reports of bisphosphonate-related ulcerative esophagitis or esophageal stricture, the patient took alendronate with little to no water or returned to a supine position too soon after swallowing the tablet.[7] Women with a history of upper GI disease or patients with gastroesophageal reflux disease also appear to be at greater risk for esophageal complications from bisphosphonates.[8] When used in combination, NSAIDs and bisphosphonates appear to have a synergistic effect on the risk for the development of gastric ulceration.[47]

MORBIDITY AND MORTALITY

Although some drug-induced upper GI ulceration may be relatively insignificant and transient, there is always a risk of severe complications including perforation, penetration of an ulcer from the stomach or duodenum into an adjacent organ, GI obstruction, and bleeding. Any of these complications can necessitate hospitalization with possible surgical intervention and can be life-threatening.

The highest rates of complication are associated with NSAIDs. Problems range from minor but common side effects such as dyspepsia and abdominal pain to the more severe complications of ulceration, perforation, and bleeding. Although the more serious complications are relatively uncommon, they are a major public concern because of the large numbers of patients who are exposed each year to aspirin and other NSAIDs. With an estimated 111 million Americans taking NSAIDs, the reported 2–4.5% rate of significant upper GI events results in a large number of patients requiring care.[44,48,49] Although estimates vary, NSAID-related mortality has been reported to be as high as 16,500 per year in the United States.[16] When nonaspirin NSAIDs are used concomitantly with aspirin, the annual risk of upper GI events increases to 5.6%.[44]

Studies have attempted to determine hospitalization rates due to NSAID-induced complications. Patients with upper GI symptoms who were admitted through emergency departments were more likely to be NSAID users as compared with controls (odds ratio = 2.4).[50] Blood transfusion requirements were also higher in the NSAID user group. Another population-based study reported a hospitalization rate of 2% over a 3-year period among NSAID users >50 years old.[51] Eighteen hospitals in Spain and Italy participated in a study of risk for upper GI bleeding in which the incidence of upper GI bleed was 401.4 per million inhabitants aged 18 and older, with 38% of the cases attributable to NSAIDs.[52] An observational study of NSAID-related GI complications and death included patients in more than 200 hospitals in the Spanish National Health System that provides care for 80% of the country.[53] The mortality was reported to be 15.3 deaths per 100,000 NSAID users.

Table 35-6 Approaches to Help Prevent Drug-Induced Upper Gastrointestinal Ulceration

Aspirin[2,6]

- Use lowest possible dose; avoid other ulcerogenic medications

Bisphosphonates[3,6]

- Take with 8 ounces of water; remain upright for at least 30 minutes after taking medication

Corticosteroids[3]

- Avoid concomitant use of nonsteroidal anti-inflammatory drugs or aspirin, if possible

Nonsteroidal anti-inflammatory drugs (NSAIDs)[3,6]

- Use lowest possible dose; use least ulcerogenic nonsteroidal anti-inflammatory drug
- Consider addition of proton pump inhibitor or misoprostol
- Avoid other ulcerogenic medications
- Treat *Helicobacter pylori* if found

Potassium chloride (oral)[6]

- Use preferred microencapsulated or liquid formulation; avoid slow-release, wax-matrix formulations

Selective serotonin reuptake inhibitors[18,19]

- Use alternative class of antidepressant; avoid concomitant use of NSAIDs, if possible

Tetracyclines[3]

- Use tablet formulation rather than capsule formulation

PREVENTION

Approaches to help prevent drug-induced upper GI ulceration are listed in **Table 35-6**.[2,3,6,18,19] The first and most important step is to avoid agents known to increase the risk of disease in patients who already have known risk factors. Whenever possible, an alternative medication with little or no risk for upper GI ulceration should be used in these patients. An example might be using acetaminophen instead of aspirin to treat osteoarthritis in an elderly patient.

When the use of a medication known to cause upper GI ulceration cannot be avoided, using the lowest possible dose is helpful. Several strategies are available to help minimize upper GI injury in patients who require NSAID therapy. Eradication of *H. pylori* infection before starting NSAID therapy reduces the risk of ulceration and related bleeding. Randomized controlled trials, however, indicate that *H. pylori* eradication does not reduce the incidence of new peptic ulcers in chronic NSAID users.[24] In low-risk patients (those having no known risk factors), using the lowest dose possible and avoiding concomitant use of other agents known to cause upper GI ulceration is recommended.[40] An increased risk of GI toxicity has been seen when aspirin (even low-dose aspirin) is combined with other NSAIDs. Likewise, corticosteroids have a low incidence of GI ulceration when used alone; however, the incidence increases significantly when combined with NSAIDs.

In patients at moderate risk (one or two risk factors), concomitant treatment with acid suppression therapy, such as a proton pump inhibitor (PPI) or misoprostol, should be considered.[40] There is a large body of evidence to support the use of these agents, but it is estimated that over 50% of NSAID users with an increased risk for GI complications do not receive a gastroprotective therapy.[28] PPIs prevent upper GI toxicity associated with NSAIDs and are generally well tolerated. They are considered effective in terms of acid suppression and prevention of peptic ulcers when coadministered with NSAIDs.[29] PPIs may be especially important for patients with a true need for aspirin therapy, such as those at risk for a secondary cardiovascular event. In these patients, PPIs have been shown to reduce rates of aspirin discontinuation by decreasing the incidence of upper GI tract adverse events.[23] Misoprostol is effective in increasing mucosal blood flow and stimulating mucus and bicarbonate production in the upper GI tract, and has been shown to reduce NSAID-induced GI ulceration considerably.[29] However, it is associated with numerous adverse effects, such as diarrhea, which can limit its routine use. The use of a selective COX-2 inhibitor, such as celecoxib, may be considered in some patients. Selective COX-2 inhibitors reduce the incidence of GI toxicity as compared with traditional NSAIDs while still maintaining the anti-inflammatory properties. However, other toxicities, such as cardiovascular risk, associated with COX-2 selective inhibitors must be weighed against the potential benefit. Other options include using NSAIDs that undergo less enterohepatic circulation, such as nabumetone or etodolac.

High-risk patients (greater than three risk factors or concomitant use of aspirin, corticosteroids, or warfarin) may benefit from the addition of a PPI or misoprostol.[40] In the highest-risk patients (history of recent ulcer complications), it is best to avoid NSAIDs altogether. If avoidance is not possible, these patients should also receive a PPI or misoprostol.[40] It is recommended that patients at high risk for ulcer-related bleeding from NSAIDs should take a PPI for as long as they continue to take NSAIDs. For patients who are able to discontinue the offending agents, short-term therapy with PPIs is preferred over longer-term therapy.[54]

When PPI therapy is indicated to either treat or to provide prophylaxis against NSAID-induced ulceration, the risks and benefits should be considered. PPIs have been associated with *Clostridium difficile* infection, acute kidney injuries, and increased risk of bone fractures. There is evidence to suggest they may also be linked to dementia, small intestine bacterial overgrowth, pneumonia, and micronutrient deficiencies. Risks of these adverse effects are greatest during long-term therapy. When long-term therapy is indicated, as with the high-risk patients mentioned above, the dose should be evaluated periodically so that the lowest effective dose can be prescribed.[54]

With other medications that cause upper GI ulceration, changing to an agent less likely to cause injury may be an option. In patients requiring oral potassium supplementation, switching to a microencapsulated form may be preferable to a slow-release, wax-matrix form. If patients are able to tolerate the taste, liquid formulations of potassium are also less likely to cause injury. Patients requiring a bisphosphonate for osteoporosis may tolerate risedronate better than alendronate, because it appears to be less ulcerogenic.

Education is important for prevention of pill-induced esophagitis. Patients should sit or stand upright and take medications with ample fluids. They should remain upright for at least 15 minutes after taking the medication. Careful selection of the dosage form of the medication may also help prevent mucosal injury. Liquid or tablet formulations may be less problematic than capsules.

In addition to the steps outlined above, patients at risk for upper GI ulceration should be educated regarding important lifestyle modifications, including avoidance of acidic beverages (e.g., citrus juices) and irritating foods (e.g., onions, spicy foods).

MANAGEMENT

The first step in the management of drug-induced upper GI ulceration is to reassess the need for the offending agent. Changing to an alternative medication is often ideal; however, if this is not possible, the lowest possible dose of the offending agent should be used. Gastric ulceration should be confirmed via endoscopy and, when present, treated with acid-suppressing therapy such as a PPI. Treatment of *H. pylori* infections should be considered as eradication can reduce the risk for further complications, such as bleeding.[29] Surgery may be necessary to treat strictures. The addition of a PPI to a patient's therapy may permit re-challenge with a medication that has previously caused GI ulceration.[55]

With pill-induced esophagitis, discontinuation of the offending agent is often the best treatment option. Symptoms usually improve within 2–6 days after stopping the medication. Antacids may provide rapid relief of pain and a topical anesthetic (e.g., viscous lidocaine) can also provide relief.[10,46] Acid suppressing therapy (e.g., PPI) may be used as an adjunct in treating esophageal damage and is beneficial if gastroesophageal reflux is present, as the refluxed material may worsen esophagitis.[10] Sucralfate may also be an option to reduce exposure of the injured mucosa to refluxed acids.[46] Avoiding foods or beverages (e.g., citrus, alcohol) that might exacerbate symptoms may also be helpful in selected patients.[10] Drinking plenty of water is also helpful in preventing tablets or capsules from adhering to the mucosa and causing damage.

INFORMATION FOR PATIENTS

Patient consultation is essential to help ensure the safe use of the medications known to cause upper GI ulceration. As previously noted, one of the biggest risk factors for drug-induced upper GI ulceration is the concomitant use of NSAIDs, including low-dose aspirin, with any other medication known to cause upper GI ulceration. Because many NSAIDs are available over the counter under a variety of brand names and as combination products, an informed patient may be the best protection against these adverse events. Patients should be reminded to carefully read labels of nonprescription medications to avoid inadvertently purchasing products containing NSAIDs. A discussion of potentially harmful nonprescription medications should be conducted with all patients receiving a prescription for any of the causative drugs. Patients should also be instructed to always use one pharmacy so that any potential interactions or additive toxicities are brought to the pharmacist's attention.

For NSAIDs, patients should take the recommended dose for the indicated length of time. If prescribed for a chronic condition, patients should be regularly reminded of the warning signs of ulceration. They should report any nausea, abdominal pain or tenderness, or coffee-ground or bloody emesis or stools immediately to their healthcare provider. Patients must realize that even low-dose aspirin can result in complications. When treating patients with acute pain, the benefits of analgesia from NSAIDs must be weighed against the aforementioned risks. Although patients and providers are often wary of the risk of developing addiction and substance abuse disorder, therapy with opioids may be more appropriate than NSAIDs in the short term in many cases.

Patients taking bisphosphonates should strictly adhere to recommendations regarding administration, including taking the medication first thing in the morning at least 30 minutes before eating or drinking anything, taking the medication with a full glass of water, and staying in a sitting or standing position for at least 30 minutes following ingestion. Patients should also be educated as to the temporal relationship that often exists between taking the medication and the onset of symptoms, so they may realize the cause and seek medical attention more quickly. Any medication known to cause pill-induced esophagitis should be taken with sufficient fluid every time a dose is administered.

CHAPTER 36

Diarrhea

Sarah A. Nisly and Alison M. Walton

Diarrhea is a relatively frequent adverse drug effect. Symptoms may be mild and transient, disappearing within days, or severe and life-threatening, causing electrolyte disturbances and dehydration. Because even healthy individuals may experience symptoms of diarrhea from time to time, the identification of drug-induced diarrhea can be challenging. In addition, drug-induced diarrhea may present after months of routine drug use, further complicating its recognition.

CAUSATIVE AGENTS

Drug classes and specific agents with a >10% incidence of diarrhea are listed in **Table 36-1**.[1-120] However, this list should not be interpreted as exhaustive, because diarrhea can be a side effect of a multitude of drugs. Agents from the following drug classes are common culprits: antibiotics, antidepressants, antihyperglycemic agents, and antineoplastics.[2-47,49-87]

Antineoplastics represent an important class of drugs associated with a high incidence of drug-induced diarrhea, referred to as cancer treatment–induced diarrhea (CTID).[121-123] The actual incidence of diarrhea associated with individual antineoplastic drugs is difficult to determine because most chemotherapeutic regimens use combination therapies; however, it is reported that between 50% and 80% of patients experience diarrhea during treatment.[123] The potential for CTID increases with the number of antineoplastic agents administered and when radiation therapy is used.[121-123]

Antibiotics also represent a class of drugs with a high incidence (>20%) of drug-induced diarrhea, referred to as antibiotic-associated diarrhea (AAD).[124-126] The incidence of AAD is similar with oral and parenteral antibiotic administration.[127] AAD can be due to a secondary *Clostridium difficile* infection (CDI) or may be a manifestation of alterations in colonic flora.[124,127] Pseudomembraneous colitis, attributed to CDI, specifically describes the formation and proliferation of membranous exudates in the colon resulting in diarrhea. Clindamycin, β-lactams, and fluoroquinolones are most frequently associated with CDI, often resulting in hospitalization and, if untreated, death.[124,126-128]

Table 36-1 Agents Implicated in Drug-Induced Diarrhea

Drug Class	Incidence	Level of Evidence[a]
ANTIBIOTICS		
Carbapenems[2-4]	3–10%	A
Cephalosporins[5-14]	10–30%	A
Clindamycin[15-20]	2–31%	A
Fluoroquinolones[21-22]	5–10%	A
Macrolides[23-28]	5–11.6%	A
Penicillins[23,29-41]	5–29%	A
ANTIDEPRESSANTS		
Selective serotonin reuptake inhibitors[21,42-44]	11–18%	A
Serotonin/norepinephrine reuptake inhibitors[42,45-47]	7–13%	A
ANTIHYPERGLYCEMIC AGENTS		
α-glucosidase inhibitors[49-53]	15–49%	A
Biguanides[54-55]	12.5–30%	A
Glucagon-like peptide-1 receptor agonists[56-58]	3–18%	A
ANTINEOPLASTIC AGENTS		
Monoclonal antibodies[59-67]	20–50%	A
Immune checkpoint inhibitors[68-69]	8–44%	A

Topoisomerase inhibitors[21,70-75]	20–90%	A
Tyrosine kinase inhibitors[76-89]	30–50%	A
MISCELLANEOUS		
Erythropoietin-stimulating agents[90-92]	10–20%	A
Interferon α-2B[93-94]	2–45%	A
Misoprostol[95-96]	15–50%	A
Mycophenolic acid[97-101]	27.6–51.3%	A
Orlistat[102-107]	11–20%	A
Protease inhibitors[108-116]	15–60%	A
Peginterferon α-2a[116-119]	19–31%	A

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

Herbal agents are also known to induce diarrhea and must be considered when evaluating a patient with this disorder. Commonly used herbal products associated with diarrhea include chondroitin, glucosamine, ginkgo, and saw palmetto.[129-132] Although limited research makes it difficult to determine the exact incidence of diarrhea associated with the use of herbal products, it may help to consult a natural medicine database.[133] Careful attention must also be paid to over-the-counter (OTC) products containing magnesium, sorbitol, and lactulose as each of these ingredients may lead to osmotic diarrhea. Likewise, agents used to treat or prevent constipation (e.g., mineral oil, bulk forming laxatives) may overcorrect and lead to diarrhea.[21]

EPIDEMIOLOGY

The epidemiology of diarrhea differs in developed versus developing countries. In the United States, it is estimated that 375 million episodes of acute diarrhea occur annually, with the highest prevalence in children younger than 5 years of age. Worldwide, diarrhea is reported as the second leading cause of death in children under 5 years of age.[134]

Elderly individuals are also at an increased risk, due to declining gastrointestinal (GI) tract function. Approximately 10% of individuals over 65 years of age report routine diarrhea.[135] Overall, drug-induced diarrhea accounts for approximately 7% of all adverse drug events. More than 700 drugs are associated with diarrhea, and about 25% of those are antibiotics.[114]

MECHANISMS

Diarrhea arises from various mechanisms including decreased absorption of water, electrolytes, or nutrients, active secretion into the GI tract, increased GI motility, or infection.[21,114,123,127,134] Mechanisms for drug-induced diarrhea are listed in **Table 36-2**.

Table 36-2 Mechanisms of Drug-Induced Diarrhea[8,69,118,125,129,136,139]

Drug	Mechanism
α-glucosidase inhibitors	Osmotic
Antibiotics Antineoplastics Biguanides Calcitonin Colchicine Misoprostol Olsalazine Theophylline	Secretory
Erythromycin Cisapride Metoclopramide	Motility
Antibiotics Antineoplastics	Exudative (increased active secretion)
Antibiotics (aminoglycosides, tetracyclines) Antiretroviral therapy Biguanides Cholestyramine Colchicine Orlistat	Malabsorption of fat (steatorrhea)
Antibiotics Antineoplastics Immunosuppressive agents Nonsteroidal anti-inflammatory drugs	Microbial proliferation

Decreased absorption of water may occur in association with drug-induced osmotic and secretory diarrhea. Drugs commonly used to treat constipation, such as lactulose and magnesium, affect the lumen of the gut and promote retention of water and electrolytes. Drug-induced secretory diarrhea occurs when a medication increases secretions or decreases absorption of large amounts of water and electrolytes in the gut lumen.[136] Drug-induced diarrhea has also been attributed to fat malabsorption (termed *steatorrhea*). Drugs can prevent absorption of fatty acids in the small intestine. When nonabsorbed fatty acids reach the colon, they inhibit fluid absorption and diarrhea ensues. Orlistat, a gastrointestinal lipase inhibitor, uses this principle to inhibit absorption of dietary fats for the purpose of weight loss.[100-105]

An increase in active secretion is associated with drugs that destroy the mucosa of the small and large intestine.[121-123] This exudative process causes discharge of mucus, serum proteins, and blood into the gut, altering water and electrolyte absorption. Irinotecan is a common antineoplastic agent associated with intestinal damage leading to increased colonic exudate.[123]

Drugs that increase GI motility (thereby decreasing the amount of time chyme is exposed to intestinal epithelium) cause abnormal absorption and secretion that can result in diarrhea. Prokinetic medications including metoclopramide and the macrolide antibiotic, erythromycin, are associated with this type of direct effect on the intestine.[21,114,127,136]

AAD occurs as a result of the disruption in the delicate organism balance throughout the GI tract.[137] Antibiotic exposure may result in the overgrowth of antibiotic-resistant bacteria, fungi, or toxin-producing *Clostridium difficile*. *C. difficile* secretes enterotoxin A and cytotoxin B. Enterotoxin A adheres to the brush-border membrane of enterocytes, inducing lesions and an inflammatory response. Cytotoxin B may also cause GI mucosal damage. Both toxins are necessary for the characteristic tissue damage associated with CDI.[21,138,139]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Diarrhea is defined as an increased frequency of bowel movements (≥3 per 24 hours), decreased stool consistency, and/or increased stool weight (>200 g per 24 hours).[134,140] Because bowel habits, stool characteristics, and daily stool output vary considerably among individuals and populations, diarrhea, including drug-induced diarrhea, should always be evaluated in light of the patient's age, weight, and comorbid conditions. Patients with prolonged, voluminous, bloody diarrhea or severe abdominal pain from diarrhea should be carefully evaluated. A patient may present with weight loss, weakness, orthostatic hypotension, tachycardia, electrolyte imbalances and acid–base disturbances.[134,140] Signs and symptoms of drug-induced diarrhea are listed in **Table 36-3**.

Table 36-3 Signs and Symptoms Associated with Drug-Induced Diarrhea[136,142]

- Abdominal pain
- Acid–base disorders
- Chills

- Cramping
- Dehydration
- Dizziness
- Electrolyte imbalance
- Fever
- Headache
- Hyperactive bowel sounds
- Hypotension
- Malaise
- Nausea/vomiting
- Tachycardia
- Thirst
- Weakness
- Weight loss

The clinical presentation of diarrhea may be acute or chronic, and drugs have been recognized as a cause in both. Diarrhea subsiding within 72 hours is usually considered acute; although episodes of acute diarrhea can persist for up to 14 days.[141] Patients with acute diarrhea may also experience abrupt onset of nausea, vomiting, abdominal pain, headache, fever, chills, and malaise. There may be generalized or local abdominal tenderness with hyperactive bowel sounds. Bowel movements are frequent and usually not bloody.[134,140] Patients seeking medical attention should be screened for dehydration and electrolyte imbalances. Infectious etiologies may require evaluation, although symptoms are typically self-resolving. A complete blood count to assess for leukocytosis and eosinophilia may be warranted if the patient has risk factors for a parasitic infection (e.g., recent travel).[141]

Diarrhea lasting 30 days or longer is considered chronic.[141] Chronic diarrhea involves frequent attacks over extended periods, making its cause more difficult to identify. With chronic diarrhea, patients are more likely to seek medical attention and diagnostic tests become more important.[40] A more thoughtful and systematic evaluation for possible malabsorption, food allergies, inflammatory bowel disease, and drug causes is necessary.[142] Flexible sigmoidoscopy, colonoscopy, and abdominal computed tomography may all be useful in determining abnormalities and alternate causes for chronic diarrhea (e.g., Crohn disease).[141,142]

Malabsorption of fat results in pale and voluminous stool with a stool fat content >6 g per day and a stool weight >200 g per day.[142] A stool sample is necessary to determine stool fat content and weight. If possible, sample collection over 3–5 days is preferred to reduce errors and variability, because slight increases in fecal fat not associated with fat malabsorption have been identified in patients with diarrhea. Because of the difficulty in obtaining a 3–5 day collection of stool, other diagnostic tests are often used. The Sudan III stain, acid steatocrit, and the near infrared reflectance analysis offer accurate and simplified alternatives for diagnosing steatorrhea.[143-146]

Food allergies often must be ruled out when evaluating patients for possible drug-induced diarrhea. However, this can be difficult and time-consuming, requiring a thorough patient history, stool samples, laboratory testing, and invasive procedures (e.g., colonoscopy).[147] Having a patient avoid high-risk foods on a trial basis is often an initial diagnostic approach because it is relatively easy and frequently successful. Typically gluten is the first to be removed from the diet, evaluating patient response after 2–8 weeks.[147,148] Aggressive diet restrictions may also be attempted, slowly adding back foods after symptoms resolve. Serum IgE or IgA antitissue transglutaminase (TTG) antibody testing, under the care and direction of an allergist, may also be done to identify specific food allergies.[148,149] In the case of celiac disease, the IgA TTG demonstrates a 95% specificity and sensitivity.[147]

Antineoplastic agents are well-recognized causes of drug-induced diarrhea.[123] Two National Cancer Institute–sponsored cooperative group trials of irinotecan plus high-dose fluorouracil and leucovorin for advanced colorectal cancer led to the recognition of a life-threatening GI syndrome, with symptoms including severe diarrhea, nausea, vomiting, anorexia, and abdominal cramping.[72,73,150] These symptoms were associated with severe dehydration, neutropenia, fever, and electrolyte imbalance. Severe abdominal cramping appeared to be an important early warning sign of imminent diarrhea.

Immune checkpoint inhibitors, such as cytotoxic T-lymphocyte antigen-4 and programmed cell death protein-1 antibodies, are commonly associated with diarrhea. Patients typically report an onset of diarrhea at 7 weeks with ipilimumab and nivolumab, while pembrolizumab-induced diarrhea typically occurs at 6 months. Beyond diarrhea, these agents are associated with a high incidence of enterocolitis, defined by abdominal pain, rectal bleeding, and colonic inflammation. Irrespective of the agent responsible, early detection and treatment of diarrhea is imperative to prevent life-threatening complications.[66,67,150]

AAD and CDI may occur from a few days after initiation of antibiotic therapy to 8 weeks after discontinuation of the drug.[139] Patients with CDI present with profuse diarrhea (rarely with blood) consisting of mucoid, greenish, foul-smelling, watery stools, abdominal pain, bloating, low-grade fever, and leukocytosis. Stool culture remains the gold standard for diagnosing CDI; however, testing is difficult to perform and time-consuming, and results take 24–48 hours to finalize. Rapid diagnostic testing can be used to identify the presence of *C. difficile* and associated toxins. Initial testing done using glutamate dehydrogenase (GDH) demonstrated variable sensitivity (~90%) and specificity (~91%). Development of the nucleic acid amplification test and polymerase chain reaction allowed for high sensitivity

(~90%) and specificity (~97%), replacing the GDH in practice.[138,151] Use of rapid diagnostic testing allows for quicker diagnosis and treatment, often within the same day. It is important to note that no diagnostic test available can ascertain the difference between colonization with *C. difficile* and true infection.

Differentiating between drug-induced diarrhea and other forms of diarrhea can be challenging. Practitioners should seek to identify any changes in diet (including alcohol) or drug therapy that have occurred recently and any new drugs (prescription, OTC, illicit) or herbal and nutritional supplements to which the patient has been exposed.[140] Because diarrhea may result from drug therapy started as long as 4 weeks prior to the onset of symptoms and 8 weeks following discontinuation, the temporal relationship between onset and changes in drug therapy must be carefully and thoroughly explored. Additive or synergistic effects from possible drug–drug interactions must also be considered. To help rule out common nondrug causes of diarrhea, eating habits, alcohol and caffeine consumption, and illicit drug use as well as psychosocial factors that might be affecting the patient all must be considered. Any environmental changes in the patient's home or office, recent travel or exposure to possible sources of bacterial or viral pathogens, disease processes, or comorbid complications must all be identified. Conditions to consider in the differential diagnosis of drug-induced diarrhea are listed in **Table 36-4**.

RISK FACTORS

General risk factors for diarrhea are listed in **Table 36-5**. Although specific risk factors for drug-induced diarrhea have not been identified, it can reasonably be assumed that patients are at increased risk for drug-induced diarrhea when one or more of the general risk factors are present or if multiple agents known to cause diarrhea are used concomitantly. Furthermore, because changes in bowel function or a developing GI tract put the elderly and pediatric populations at increased risk for diarrhea, healthcare providers must recognize that the potential for drug-induced diarrhea is increased in these populations as well.[123,134-136]

Table 36-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Diarrhea[21,116,123,126,136]

- Celiac disease
- Crohn disease
- Diverticulitis
- Gastroenteritis
- Infectious diarrhea/traveler's diarrhea
  - *Campylobacter*
  - *Cryptosporidium*

  - *Cyclospora*
  - Enterotoxigenic *Escherichia coli*
  - *Giardia lamblia*
  - *Microsporidia*
  - *Plesiomonas shigelloides*
  - *Rotavirus*
  - *Salmonella*
  - *Shigella*
- Irritable bowel syndrome
- Ischemic bowel disease
- Malabsorption syndrome
- Psychiatric disease
- Psychosocial/psychological disorders
- Ulcerative colitis

Table 36-5 Risk Factors for Drug-Induced Diarrhea[136-138]

- Age (pediatric and elderly)
- Diet (high-fat, high-fiber)
- Female sex
- Malnutrition
- Pain
- Unsanitary conditions

MORBIDITY AND MORTALITY

The morbidity and mortality of drug-induced diarrhea is largely unknown. Severe diarrhea may result in dehydration, electrolyte abnormalities, and shock, leading to hospitalization and even death. Worldwide, diarrhea is reported as the second leading cause of death in children under 5 years of age.[134] CDIs during hospitalization doubled between 2001 and 2010.[151] In 2009, the 30-day readmission rate for patients with *C. difficile* was 12.8%.[152] Two National Cancer Institute–sponsored cooperative group studies reported mortality rates of 0.6% and 1.9% due to severe diarrhea and subsequent complications secondary to the use of irinotecan, fluorouracil, and leucovorin in cancer patients.[68-69]

Table 36-6 Approaches to Help Prevent Drug-Induced Diarrhea[139,155,162]

- Adjust dosage to patient-specific parameters (e.g., age, weight, renal/hepatic function)
- Avoid foods with artificial sweeteners (e.g., sorbitol, mannitol, fructose)
- Encourage fluid and proper diet

- Encourage rational antibiotic use; prescribe antibiotics only when necessary; reserve broad-spectrum antibiotics where possible
- Identify any drug intolerance or allergy previously experienced
- Identify liquid medications with high sorbitol content and substitute the tablet/capsule form when possible
- Implement probiotic therapy (further investigation necessary; see text)
- Instruct patient to eat low-residual diet (e.g., bananas, rice, applesauce, toast)
- Instruct patients to consume low-fat meals (e.g., with orlistat)
- Instruct patients to eat frequent, small meals
- Instruct patients to take medication with meals (if not contraindicated)
- Slowly increase dosage of potential offending agent (if able)
- Use alternative medications with a lower risk of diarrhea when available

PREVENTION

Techniques for decreasing the risk of drug-induced diarrhea are listed in **Table 36-6**. Although proper diet and adequate fluid intake should be always be encouraged, implementing specific preventive measures in all patients receiving a drug with the potential to induce diarrhea may be overzealous. It is more effective for healthcare providers to implement preventive measures in patients with a history of intolerance to medications or in patients receiving medications associated with a high incidence of diarrhea. Whenever possible, healthcare providers should attempt to minimize drug-induced diarrhea in their patients by avoiding the use of medications with high sorbitol content or high tonicity,[153] using alternative medications with lower incidences of causing diarrhea, using low doses and slowly increasing the dose of drugs known to cause diarrhea, and judiciously prescribing antibiotics.

In addition to general measures, drug-specific preventive measures are sometimes available. Patients may decrease the incidence of orlistat-induced diarrhea by consuming low-fat meals. Patients experiencing GI cramping and diarrhea associated with iron therapy or multivitamins may benefit from taking these preparations with meals. Patients with chemotherapy-induced diarrhea may benefit from smaller, more frequent meals, avoiding certain foods known to contribute to their diarrhea, and increasing intake of oral fluids.[123]

Probiotics are commonly promoted as being effective in strengthening the immune system and/or recolonizing the gut. Patients with AAD may express interest in using probiotics or have specific questions regarding product selection.[154] The use of probiotics in the prevention and treatment of AAD has been studied. Unfortunately, the evidence is insufficient to determine which probiotics have the greatest efficacy or which antibiotic-treated AAD patients receive the greatest benefit.[155]

Probiotics have also been suggested and evaluated for use in prevention of CDI.[156-158] A Cochrane Review that pooled the findings of 23 randomized clinical trials suggested that probiotics, when given simultaneously with antibiotics, reduced the risk of CDI.[157] However, given the difficulty with interpretation from meta-analyses. Evidence remains insufficient to recommend probiotics for the prevention of CDI.[139] Probiotic use is likely safe if recommended in otherwise healthy patients. Caution should be used in patients with risk factors for probiotic sepsis, including those with immune compromise.[158]

MANAGEMENT

Approximately 90% of cases of acute diarrhea are self-limiting and require no intervention.[159] Drug-induced diarrhea usually spontaneously resolves within a few days following withdrawal of the drug and, in some cases, resolves even with continued use of the causative agent.[114] When diarrhea persists, identification of the offending agent is imperative to direct appropriate therapy. Patients should be asked specifically about new or recently discontinued drugs (prescription, OTC, or illicit) or herbal and nutritional supplements as well as changes in eating habits and alcohol or caffeine intake.[140]

Whenever possible, the culprit drug should be discontinued or changed to an agent less likely to cause diarrhea. Solid oral dosage forms may be considered when sorbitol-containing liquid medications or high-tonicity formulations are associated with diarrhea. Another option, if a formulation change is not feasible, is to dilute the liquid medication with water. When therapy with the offending agent must be continued, some of the preventive measures described in Table 36-6 may be helpful. With a few exceptions, antidiarrheal medications should not be thought of as first-line therapy for drug-induced diarrhea; however, if the culprit drug cannot be changed or discontinued and preventive measures do not resolve the diarrhea, antidiarrheal drugs may be used. The selection of the antidiarrheal drug depends on the cause of the drug-induced diarrhea (**Table 36-7**).[123,138,139]

Table 36-7 Antidiarrheal Agents Utilized in Drug-Induced Diarrhea[125,140,141]

Cause	Antidiarrheal Drug
Cancer treatment–induced diarrhea	Loperamide
	Octreotide
	Tincture of opium (persistent symptoms)
Clostridium difficile–associated diarrhea	Bismuth subsalicylate
	Cholestyramine (persistent symptoms)

CANCER TREATMENT–INDUCED DIARRHEA

Patients with CTID are a population in which antidiarrheal medications may be indicated as first-line therapy, especially in situations in which it would be detrimental to discontinue or lower the dose of the culprit chemotherapeutic agent. CTID has been recognized as a severe and life-threatening complication for which vigilant monitoring and aggressive therapy is warranted.[121-123,160-162] Patients with uncomplicated, grade 1 or 2 CTID (**Table 36-8**) should be treated with loperamide 4 mg initially followed by 2 mg every 4 hours or after every unformed stool to a maximum of 16 mg daily. Patients should be reassessed after 12–24 hours, and, if diarrhea persists, the loperamide dose should be increased to 2 mg every 2 hours and therapy with an oral antibiotic (e.g., fluoroquinolone) initiated. For patients with unresolved diarrhea after an additional 12- to 24-hour period, loperamide should be discontinued and octreotide 100–150 mcg should be given subcutaneously three times daily. The optimum dose of octreotide has not been determined; doses may be increased up to 500 mcg three times daily until symptoms are controlled with expected response within 4 days. Tincture of opium is another potential second-line antidiarrheal agent to consider in patients who do not respond to other treatment approaches. Patients presenting with grade 3 or 4 CTID should be admitted to the hospital and given intravenous fluids and antibiotics (e.g., fluoroquinolone). Octreotide in subcutaneous doses as outlined above or intravenously in a dose of 25–50 mcg per hour should be administered. Cytotoxic chemotherapy should be discontinued until all symptoms have resolved; afterward, chemotherapy should be reinstituted at reduced dosages.[121-123]

Table 36-8 Criteria for Grading Severity of Diarrhea[123-125]

	Grade 1	Grade 2	Grade 3	Grade 4
Patients without a colostomy	Increase of <4 stools/day over pretreatment No other symptoms	Increase of 4–6 stools/day or nocturnal stools Moderate cramping, not interfering with normal activity	Increase of ≥7 stools/day Severe cramping and incontinence, interfering with daily activities	>10 stools/day Grossly bloody diarrhea and need for parenteral support
Patients with a colostomy	Mild increase in loose, watery colostomy output compared with pretreatment	Moderate increase in loose, watery colostomy output compared with pretreatment, but not interfering with normal activity	Severe increase in loose, watery colostomy output compared with pretreatment, interfering with normal activity	Physiologic consequences requiring intensive care; hemodynamic collapse

Oral antibiotics (e.g., fluoroquinolone) are used in CTID to prevent superinfection from widespread necrosis of crypt stem cells, especially in patients with immunosuppression or neutropenia. Superinfection can worsen diarrhea via direct secretory effects on the intestinal mucosa and destruction of the intestinal epithelium. Antibiotic therapy should be targeted at opportunistic pathogens, including *C. difficile*, *Clostridium perfringens*, *Bacillus cereus*, *Giardia lamblia*, *Cryptosporidium, Salmonella, Shigella*, and *Campylobacter* and guided by local patterns of sensitivity and resistance.[122]

CLOSTRIDIUM DIFFICILE–ASSOCIATED DIARRHEA

In patients with CDI, the culprit antimicrobial agent(s) should be stopped as soon as possible.[138-139] Oral metronidazole and vancomycin are first-line antibiotics used to treat patients with *C. difficile* and resulting CDI. For mild-to-moderate CDI, oral metronidazole is preferred initially based on equal efficacy and decreased cost in comparison to oral vancomycin. Metronidazole should be given orally in doses of 500 mg three times a day.[139] Although oral metronidazole is preferred, intravenous metronidazole may be considered when the oral route is not available. Vancomycin therapy delivered via enema may be another appropriate option for patients in whom oral antibiotics cannot reach a segment of the colon. For severe CDI, patients should be treated with oral vancomycin 125 mg four times a day. Oral vancomycin is also recommended for patients who do not respond to initial metronidazole treatment within 5–7 days, for patients with intolerance or allergy to metronidazole, and for pregnant or breastfeeding women. Intravenous vancomycin is not indicated in treatment of CDI. In patients with severe and complicated CDI (e.g., those with hypotension or shock, ileus, megacolon), a combination regimen of oral vancomycin 500 mg four times daily in addition to intravenous metronidazole 500 mg every 8 hours may be warranted. If ileus is present, one should consider adding a vancomycin retention enema (500 mg in 500 mL normal saline) administered every 6 hours. The American College of Gastroenterology guidelines recommend a treatment duration of 10 days for initial CDI, although the Society for Healthcare Epidemiology of America and the Infectious Diseases Society of America guidelines include a range of 10–14 days.[138,139] Fidaxomicin (200 mg orally twice daily for 10 days) is an alternative antibiotic approved for the treatment of mild-to-moderate CDI; however, the cost of the agent is significantly higher than vancomycin, the efficacy is similar, and clinical practice guidelines urge caution with its use until additional data are available.[138,139,162,163] There are no convincing efficacy data to support use of other antibiotics, including rifampin, rifaximin, nitazoxanide, or tigecycline.[138,139]

Recurrence is a common challenge in the management of CDI.[139] The first recurrence of CDI should be managed with the same regimen used in the initial episode unless the disease is severe, in which case vancomycin should be used. The second recurrence should be managed with a tapered, pulsed vancomycin regimen, such as 125 mg orally four times daily for 10 days followed by 125 mg orally three times a week for 10 doses. For a third recurrence, fecal transplant should be considered.[139]

Although antibiotics are the focus in CDI management, other treatment modalities have been studied. Case reports and small case series have described use of intravenous immunoglobulin (IVIG) to bolster the immune response to *C. difficile* toxins.[139] The dosing regimen of IVIG is 300–500 mg/kg daily until resolution or to a maximum of six doses. IVIG should only be considered in select patients as an adjunct to antibiotic therapy in severe refractory or recurrent CDI.[139,164,165] Treatment directed at binding the *C. difficile* toxin has included use of the bile acid–binding resin cholestyramine. Studies, however, have failed to show a high success rate with cholestyramine, and it has been relegated to adjunct treatment status for patients who do not respond adequately to antibiotics.[164,165]

In patients with CDI, antidiarrheal medications that inhibit peristalsis (e.g., diphenoxylate) should be limited or avoided, because these agents can mask symptoms, prevent toxin elimination potentially prolonging the course of illness, and have been associated with the serious complication of toxic megacolon.[138,139] Agents such as bismuth subsalicylate are preferred in CDI if antidiarrheal treatment is necessary. Probiotics have also been studied for the treatment of CDI.[166,167] A systematic review and meta-analysis of *Saccharomyces boulardii* concluded that the evidence for efficacy in the treatment of CDI as an adjunct to antibiotics is weak.[167] The use of adjunct probiotics is not recommended for initial treatment based on limited efficacy data, high costs, potential risks, and product variability.[138,139]

REHYDRATION MANAGEMENT

The most common complication of severe diarrhea is dehydration.[134] Patients with mild or moderate dehydration can nearly always be rehydrated with oral rehydration solution (ORS). An appropriate ORS contains sodium, potassium, chloride, citrate, and glucose to address electrolyte and bicarbonate losses. The rehydration volume for dehydrated patients is approximately 50–100 mL/kg. Additional volumes may be necessary to account for continuing stool losses.[134]

Intravenous fluid is recommended for patients with severe dehydration or when oral rehydration is contraindicated.[134] Volumes of 100 mL/kg of body weight or more may be required for rehydration. Rapid replacement of fluid and electrolyte losses is necessary to prevent shock and subsequent death. A polyelectrolyte solution such as Ringer’s lactate is considered appropriate for this purpose. Normal saline is a poorer choice for rehydration in these patients because it does not correct the acidosis or hypokalemia that may result from severe diarrhea.[134]

INFORMATION FOR PATIENTS

Patients prescribed drugs that may cause clinically relevant diarrhea should be warned of the potential for this adverse effect prior to the initiation of therapy. A detailed list of potential adverse effects with a timeline should be communicated and strategies to combat symptoms that arise discussed. To help anticipate and avoid complications, patients should always be carefully questioned regarding any adverse drug reactions previously experienced.

Adequate fluid intake and a proper diet should be recommended for any patient who might experience drug-induced diarrhea. Use of OTC agents to alleviate diarrhea may be appropriate. Patients with CDI should be cautioned to avoid antidiarrheals, as use can retain toxins produced by *C. difficile* within the colon. Probiotics may be useful in AAD, and it is reasonable to recommend a product in an otherwise healthy patient.

Patients should be aware that most incidences of drug-induced diarrhea are self-limiting and resolve within a few days. However, if symptoms are chronic, lasting more than 30 days, or severe (e.g., presence of blood, existence of fever, excruciating pain), the patient should notify the healthcare provider immediately.

Note: The authors wish to acknowledge the work of Dr. Nayahmka McGriff-Lee, who authored this chapter in a previous edition.

CHAPTER 37

Constipation

Sarah A. Nisly and Carolyn M. Jung

Constipation is a common gastrointestinal disorder and is frequently drug induced. Signs and symptoms vary considerably between patients. Although constipation is often relatively mild and interferes only slightly with a patient's quality of life, it can, at times, necessitate discontinuation of essential drug therapy, increase the cost of care, and even prove to be life threatening. Identification of drug-induced constipation is difficult due to a number of confounders which may contribute to or exacerbate the problem. In addition, there is significant variation among both patients and health professionals in defining what actually constitutes constipation.

CAUSATIVE AGENTS

Commonly used drugs known to be associated with a 10% or greater incidence of causing constipation are listed in **Table 37-1**.[1-57] Constipation is commonly listed as an adverse effect for both prescription and nonprescription medications; thus, this list should not be considered all-encompassing. Opioids and antineoplastic agents are two of the most common classes of medications known to cause constipation.[20-29,46-55] Any medication with anticholinergic properties, including antidepressants and antipsychotics, has the potential to cause constipation as well.[4-13,32-38] Medication classes with lower incidences of constipation include anticonvulsants, antihistamines, nondihydropyridine calcium channel blockers, diuretics, calcium supplements, and aluminum-containing antacids.[58-66] Some medications within these classes may have higher incidences of constipation similar to those of opioids. Herbal preparations including chondroitin sulfate, glucosamine sulfate, *Echinacea*, and saw palmetto have also been reported to cause constipation.[67-80]

EPIDEMIOLOGY

The reported prevalence of constipation due to any cause varies considerably among published studies. A systematic review of published literature on constipation found a median prevalence of 16% in North America, but ranges between 2.5% and 79% worldwide.[81] Females experience constipation more commonly than males, with a median ratio of 1.5:1 cases.[81,82] Females are also more likely to seek medical care for constipation and receive treatment, as opposed to males. The prevalence of constipation increases with age, with 33.5% of adults ages 60–101 affected.[81] Within the geriatric population, nursing home residents experience constipation more often than the general community. Lastly, ethnicity may play a role with nonwhites more likely to be affected by constipation than whites.[81,82] Although drugs are well recognized as a potential cause of constipation, the incidence of drug-induced constipation is unknown. Opioid-induced constipation, a subset of drug-induced constipation, occurs in 17–67% of patients in the United States according to survey and medical chart review data.[83]

Table 37-1 Agents Implicated in Drug-Induced Constipation

Drug Class	Example(s) (% incidence)	Level of Evidence[a]
Antibiotics	Dalbavancin[2] (18.2%)	A
Anticholinergic agents	Solifenacin[3] (13–16%)	A
Antidepressants	Bupropion[4,5] (5–10%)	A
	Duloxetine[6,7] (5–15%)	A
	Fluoxetine[8,9] (4–17.9%)	A
	Imipramine[10,11] (20%)	A
	Paroxetine[4,11,12] (18–25%)	A
		A

	Venlafaxine[4,13] (15%)	
Antihypertensives	Clonidine[14,15] (1–10%)	A
	Guanfacine[17] (10–15%)	A
	Verapamil[18,19] (7.3–42%)	A
Antineoplastic agents	Abiraterone[20] (23%)	A
	Ado-Trastuzumab[21] (26.5%)	A
	Axatinib[22] (20%)	A
	Bevacizumab[23] (29–40%)	A
	Bicalutamide[24-26] (22%)	A
	Decitabine[27] (11%)	A
	Doxorubicin[28] (41%)	A
	Temsirolimus[29] (20%)	A
	Thalidomide[30-31] (54%)	A
Antipsychotics	Aripiprazole[32-34] (8–13%)	A
	Clozapine[35,36] (14%)	A
	Olanzapine[35,36] (5–15%)	A
	Quetiapine[37,38] (8–10%)	A
Bile acid sequestrants	Colesevelam[39] (8.7–11%)	A
	Colestipol[40] (10%)	A
Bisphosphonates	Zoledronic acid[41,42] (6–27%)	B
Diuretics	Furosemide[16] (29.2%)	B
HMG-CoA reductase inhibitors	Atorvastatin[16] (21.4%)	B
Immunologic agents	Belatacept[43] (33%)	A
Iron preparations	Various salts[44,45] (15.6%)	A
NSAIDs	Ibuprofen[16] (19.4%)	B
Opioids	Codeine[46-48] (10–21%)	A
	Fentanyl[49,50] (8–26%)	A
	Hydrocodone[48,51] (10–29%)	A
	Hydromorphone[52] (29%)	A
	Methadone[53] (20%)	A
	Morphine[50,54,55] (5.1–57%)	A
5-HT$_3$ antagonists	Alosetron[56] (32%)	A
		A

	Granisetron[57] (3–18%)	
Miscellaneous	Ursodiol[1] (9.7–26.4%)	B

NSAID = nonsteroidal anti-inflammatory drug.
[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

MECHANISMS

Chronic constipation is differentiated into five types and mechanisms vary with each type. Primary constipation disorders include normal transit constipation (NTC), slow transit constipation (STC), pelvic floor dysfunction or defecatory disorders, and combination disorders. Colonic motility disorders such as NTC or STC are associated with decreased function of the colon, although many of the changes that occur with STC cause or are a consequence of chronic constipation.[84] Defecatory or pelvic floor disorders result from structural abnormalities within the colon or rectum.[82,85] Drug-induced constipation, as well as mechanical obstruction and constipation due to systemic disease, are all considered secondary constipation disorders. Mechanisms of drug-induced constipation differ based on the implicated drug class. Opioid-induced constipation results in decreased gastrointestinal motility both through effects on the central nervous system and binding of opioid receptors in the intestines.[86] In contrast, furosemide is thought to mediate constipation through simple dehydration.[16] Common mechanisms for drug-induced constipation are listed in **Table 37-2**.[16,82,85,86]

Table 37-2 Mechanisms of Drug-Induced Constipation

Drug	Mechanism
Diuretics	Decreased fluid secretion
Drugs with anticholinergic properties (examples include antihistamines, antidepressants)	Parasympatholytic actions affecting innervation of many regions of the gastrointestinal tract
Opioids and related compounds	Inhibition of acetylcholine release from the central nervous system Prolongation of intestinal transient time (reduced peristalsis) Increased electrolyte and water reabsorption

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Bowel symptoms such as hard or infrequent stools or incomplete rectal evacuation constitute the syndrome of constipation. Patients and practitioners may describe constipation with additional symptoms such as the inability to defecate at will, excessive straining, bloating, and abdominal pain or distention.[82,87] The Rome III symptom criteria for chronic constipation take into consideration the variety of symptoms with which patients may present. Symptoms must be present for at least 6 months prior to diagnosis and two or more symptoms must occur in a quarter of defecation episodes in the past 3 months. Symptoms include straining, lumpy or hard stools, sensation of incomplete evacuation, feeling of anorectal obstruction, use of manual maneuvers to stimulate defecation, less than three bowel movements per week, and absence of loose stools with lack of diagnostic criteria for irritable bowel syndrome.[87] Signs and symptoms associated with drug-induced constipation are presented in **Table 37-3**.[82,87] The onset of drug-induced constipation is highly variable.

Differentiating between drug-induced constipation and other potential causes is important to the determination of appropriate treatment and/or methods of prevention.[85] **Table 37-4** lists conditions to consider in the differential diagnosis of drug-induced constipation. A detailed history including bowel habits and the onset of constipation with relation to any risk factors should be obtained from the patient. Patients should be encouraged to complete a stool diary and chart dietary habits and medications to help in the identification of any potential correlations. The medication history should document the patient's use of prescription drugs, nonprescription drugs, and nutritional supplements. Also, a temporal relationship between changes in therapy and onset of symptoms should be carefully explored. Additive or synergistic effects of medications to which the patient has been exposed must be considered and ruled out as a possible cause of constipation. Assessment of the patient's hydration status and mobility can help rule out other common causes of constipation. Psychosocial factors, changes in the home or office environment, other disease processes or comorbid conditions can also lead to constipation and should be assessed.[85]

Table 37-3 Signs and Symptoms Associated with Drug-Induced Constipation[a]

- Abdominal pain
- Anal or perianal pain
- Anal prolapse/hemorrhoids
- Anorexia
- Bloating

- Cramping
- Discomfort
- Feeling of fullness
- Hypoperistalsis
- Ineffective straining
- Infrequent bowel movements
- Lack of bowel sounds
- Local distention
- Nausea/vomiting
- No urge to defecate
- Sense of incomplete evacuation
- Sense of anal blockage/obstruction
- Stools difficult to pass (small, hard, dry)
- Weight loss

[a] Severe abdominal pain, weight loss >10 lb, hematochezia, positive fecal occult test, unexplained anemia or sudden change in stools constitute "Alarm Symptoms" and these patients should be referred immediately to a proper source of care.

Table 37-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Constipation

- Dehydration
- Diabetes mellitus
- Disorders of bowel structure/function
- Diverticulitis
- Hypercalcemia
- Hypothyroidism
- Irritable bowel syndrome
- Ischemic bowel disease
- Malignancy
- Mechanical obstruction
- Neuropathic diseases
- Pregnancy
- Psychiatric disease
- Psychosocial/psychological disorders

Severe abdominal pain, unintended weight loss (>10 lb), hematochezia, positive occult-blood test, unexplained anemia, sudden change in stools (e.g., changes in consistency, color, or appearance), a family history of colorectal cancer, or a combination of any of these, should be considered alarm symptoms and receive careful attention during the evaluation.[82] Gastrointestinal endoscopy or imaging via computerized tomography scan should be considered to help rule out malignancy in patients presenting with these symptoms. A rectal examination can help identify some anatomical complications (e.g., pelvic floor dysfunction) associated with constipation.[82]

Table 37-5 Risk Factors for Drug-Induced Constipation

- Age (elderly)
- Concurrent medications which may provide an additive effect
- Dehydration
- Female sex
- Inactivity
- Poor diet
- Pregnancy

RISK FACTORS

Patient parameters and comorbid disease states that place patients at increased risk for constipation are listed in **Table 37-5**.[61,82,88] Certain drugs are notorious for causing constipation (e.g., opioids).[88] Opioid-induced constipation (OIC) is associated with longer durations of therapy and concurrent use of multiple opioids.[89,90] The incidence of drug-induced constipation may be increased in the elderly because of an associated decline in bowel function (e.g., decreased transit time).[91]

MORBIDITY AND MORTALITY

Constipation drastically alters quality of life, affecting mood, mobility, work, recreation, and enjoyment of life.[92-94] Constipation associated with opioid use has been reported in 40% and 60% of opioid users for noncancer and cancer pain, respectively.[95,96] Severe constipation may result in small bowel obstruction, impaction, gastrointestinal perforation, and death. Chronic constipation has also been associated with an increased mortality and decreased quality of life.[97,98] The advent of new and novel treatment options for constipation has led to an increased cost for treatment; however, up to 56% of patients remain unsatisfied with their treatment regimen.[96] Reports suggest there are over 6 million ambulatory care visits annually due to constipation, leading to estimated direct costs of $1.6 billion.[99] Additionally, over $800 million is spent annually within the United States on over-the-counter treatment of constipation.[100] In one 12-month analysis, OIC was associated with a 109% increase in overall healthcare costs.[89]

PREVENTION

Techniques for decreasing the risk of drug-induced constipation are listed in **Table 37-6**.[91,101-103] Patients may decrease risk by staying active, maintaining a routine bowel habit schedule, drinking plenty of fluids, and eating a balanced, high-fiber diet. Healthcare providers may further decrease or prevent drug-induced constipation in their patients by adjusting doses of causative agents with respect to specific patient parameters, using the lowest possible effective dose of the drug to treat the patient, slowly escalating the doses of medications to allow for better tolerance, and using alternative medications with a lower risk of constipation. In patients beginning chronic opioid therapy, careful attention must be paid to the possibility of OIC. Initiation of a prophylactic bowel regimen, using a stimulant laxative alone or in combination, is appropriate in high-risk patients or those anticipated to receive long-term opioid therapy.[91,101-103]

Table 37-6 Approaches to Help Prevent Drug-Induced Constipation

- Adjust dosage to patient specific parameters (e.g., age, weight, renal/hepatic function)
- Encourage activity (exercise, especially aerobic)
- Encourage fluids and high-fiber diet (25–35 g/day of fiber for adults)
- Encourage patients to avoid postponing defecation
- Identify any intolerance already experienced to drugs
- Maintain a routine bowel habit schedule
- Slowly escalate doses to allow for better patient tolerance
- Use alternative medications with a lower risk of constipation

MANAGEMENT

Patients presenting with chronic constipation, severe pain, hematochezia, or fever should be evaluated for small-bowel obstruction, impaction, or gastrointestinal perforation.[87] Whenever possible and appropriate, the culprit drug should be discontinued and an alternative agent less likely to cause constipation substituted.[91,101] When that is not possible, lowering the dose of the drug may help relieve symptoms. Lifestyle modifications, including dietary changes (increasing consumption of fruits, vegetables, and other dietary sources of fiber), increasing fluid consumption, and increasing physical activity, can sometimes also be helpful. Removal of the offending agent and/or implementation of lifestyle changes may take weeks to relieve constipation. Providing thorough patient education and creating realistic patient expectations are keys to successful treatment of this drug-induced disease.[91,101] Discontinuation of agents inducing constipation is not always feasible, and patients may need to weigh the benefits of that agent (e.g., pain control) with the ongoing risk of persistent constipation and quality of life indicators.

Pharmacotherapy may be implemented if dietary and lifestyle modifications do not relieve the constipation.[90,96,101,104-106] Table 37-7 lists possible agents for use and the corresponding mechanisms of action. Bulk-forming agents, emollient laxatives, osmotic laxatives, and saline laxatives modify the characteristics of stool to increase bulk, decrease consistency, or facilitate passage through the digestive tract and anus. Stimulant laxatives and chloride channel agonists accelerate transit time and facilitate evacuation of stool from the rectal vault. Agent selection should be carefully matched to the root drug cause of constipation and anticipated duration of therapy.[90,96,101,104-106]

Table 37-7 Drugs Used to Treat Drug-Induced Constipation

Agent	Generic Name	Mechanism of Action
Emollient laxative	Docusate sodium	Soften stool Stimulate net intestinal secretion Surfactant properties
Fiber, bulk-forming laxatives	Methylcellulose Calcium polycarbophil Psyllium	Increase stool weight Modify stool consistency
Lubricant laxatives	Mineral oil	Facilitates transit by coating feces
Miscellaneous	Lubiprostone Prucalopride Tegaserod	Increases intestinal fluid secretion via activation of the chloride channel Stimulates intestinal secretions and peristalsis through activation of the 5-HT$_4$ receptor
Nonselective opioid antagonist	Naloxone Nalmefene	Opioid receptor antagonist in the gastrointestinal tract Crosses the blood–brain barrier and may reverse opioid analgesic effects
Osmotic laxatives	Glycerin Lactulose Phosphate salts Polyethylene glycol	Attract and retain water in intestinal lumen Increases intraluminal pressure Exert an osmotic effect Stimulate colonic motility (lactulose)
PAMORA	Alvimopan Methylnaltrexone Naloxegol	Antagonize opioid receptors in the gastrointestinal tract. Do not cross the blood–brain barrier; do not reverse opioid analgesic effects.
Saline laxative	Magnesium salts	Fluid osmotically drawn into small intestine; cholecystokinin-stimulated
Stimulants	Bisacodyl Senna	Stimulate intestinal motor activity Stimulate net intestinal secretion Increase stool volume/weight Induces urge to defecate

$5\text{-}HT_4$ = 5-hydroxytryptamine (4), PAMORA = peripheral acting mu-opoid receptor antagonist.

Bulk-forming agents and osmotic laxatives are generally used first-line; however, stimulant laxatives may be used when patients do not respond adequately to bulk or osmotic laxatives given alone.[96,101,104] Exaggerated concerns regarding stimulant laxative abuse have led to hesitation on the part of healthcare providers to use this class of laxatives. Caution should be exercised when a valid concern for abuse or misuse exists (e.g., anorexic patients).

Peripheral acting mu-opioid receptor antagonists (PAMORA), developed specifically for the treatment of OIC, include alvimopan, methylnaltrexone, and naloxegol.[90,96,105] These agents work to target opioid receptors specific to the gastrointestinal tract, thus blocking the constipating effects of systemic opioids. This mechanism is more specific than that of naloxone or nalmefene, which reverse both peripheral and central opioid effects, thereby relieving symptoms of OIC but also potentially reversing the intended opioid analgesic effects.[107,108] Lubiprostone is an additional agent used for OIC and is considered a PAMORA, although the mechanism is through chloride channel activation.[109] Axelopran and sustained-release naloxone are two new PAMORAs in clinical trials for OIC.[109] Successful bowel evacuation is reported to occur in up to 35% of patients receiving one of the newer PAMORA agents.[96,109] Flatulence and diarrhea are the most common adverse events with PAMORA, although abdominal pain can occur. Dosage forms and agent-specific safety concerns should be considered when evaluating treatment options. Methylnaltrexone, for example, is only available as a subcutaneous injection, making this agent less advantageous for routine outpatient use.[96] Alvimopan carries a U.S. Food and Drug Administration “black box warning” for risk of myocardial infarction and has restricted distribution requirements.[109]

INFORMATION FOR PATIENTS

Fluids and a proper diet, including fiber consumption of at least 25 g/day, should be recommended for any patient at risk for drug-induced constipation. Patients should be instructed to maintain regular bowel habits and not to ignore the urge to defecate. Increased activity and exercise should be encouraged. Continued evaluation of the appropriateness of the offending medication is warranted and initiation of drug therapy treatment may be necessary if and when lifestyle and dietary measures do not resolve constipation. If symptoms of abdominal distention, severe pain, hematochezia, unintentional weight loss >10 pounds, or fever occur, the patient should notify a healthcare provider immediately for evaluation and assistance.

CHAPTER 38

Hepatic and Cholestatic Diseases

Scott S. Malinowski and Daniel M. Riche

The liver is the body's most important organ in terms of metabolism and elimination of drugs and other chemical substances. The nature of these functions makes the liver inherently susceptible to toxicity from foreign substances (xenobiotics). In light of this and because of its many other critical functions, damage to the liver carries significant risk for morbidity and mortality. Hepatic and cholestatic (hepatocholestatic) injury is a well-documented result of many drugs taken or administered in excessive quantities but can also occur with some drugs at usual or even low therapeutic doses (idiosyncratic reactions). Although pharmaceutical agents are the focus of this chapter, herbal and natural products, illicit drugs, and other environmental chemicals are discussed where appropriate.

CAUSATIVE AGENTS

Over 1,100 chemical agents are associated with the potential to cause significant hepatocholestatic injury. **Table 38-1** lists medicinal and illicit drugs, herbal products, and chemical agents implicated in drug-induced hepatocholestatic diseases.[1-48] An excellent public domain online resource is the LiverTox Database (www.livertox.nih.gov), sponsored by the National Institute of Diabetes and

Digestive and Kidney Diseases and the National Library of Medicine. This searchable website provides up-to-date information on medications and dietary supplements associated with drug-induced liver disease.[49]

The predominant pathologic pattern of injury serves as the basis for the categorization of the various types of drug-induced hepatocholestatic diseases. The categories of injury are hepatocellular (which is also called cytoxic and includes necrosis, apoptosis, and steatosis), cholestatic, vascular, and neoplastic. The pathophysiologies of these categories are discussed in further detail in the Mechanisms section of this chapter. Agents and classes of agents corresponding with each category are described in **Table 38-2**.[1-14,17-21,25,33,43,47,50-58]

EPIDEMIOLOGY

As the availability and use of drugs and herbal remedies increase, so too does the risk and incidence of drug-induced hepatocholestatic disease. Hepatotoxicity is a common reason for withdrawal of drugs from the market and, due largely to the inability of premarketing trials to detect rare events, is usually discovered during postmarketing surveillance. Accurately determining the incidence of drug-induced liver injury has been problematic due to a number of factors, including unknown numbers of overall populations exposed, lack of simple objective diagnostic tests, difficulty in attributing causation to a single drug for people taking multiple medications, and a lack of systematic reporting.[34]

Table 38-1 Agents Implicated in Drug-Induced Hepatic and Cholestatic Diseases

Drug	Incidence	Level of Evidence[a]
ANALGESICS/ANTI-INFLAMMATORY AGENTS		
Acetaminophen[1-16]	NK	B
Aspirin[1-18]	NK	C
Bromfenac[19]	NK	C
Celecoxib[15,16,20,21]	NK	C
Diclofenac[1-16,22,23]	0.001–0.005%	B
Etodolac[1-16]	NK	C
Ibuprofen[1-16,20,21]	NK	C
Indomethacin[22]	NK	C

Ketorolac22	NK	C
Leflunamide1-16	4.4%	A
Naproxen20,21	NK	C
Nimesulide1-16	NK	C
Oxaprozin1-16	NK	C
Phenylbutazone1-14,20,21,24	NK	C
Piroxicam1-18	NK	C
Propoxyphene1-14,17,18	NK	C
Propionic acid derivatives1-18	NK	B
Sulindac15,20,21,24	NK	C
Tolmetin1-18	NK	C
ANTIMICROBIAL AGENTS		
Amoxicillin25	0.003%	C
Ampicillin1-14,20-22,27,28	NK	C
Amoxicillin–clavulanate1-14,20-22,26-28	0.0099–0.017%	C
Amphotericin1-14,26-28	NK	C
Antimonial antiparasitics1-14,17,18,27,28	NK	C
Azole antifungals1-14,20-22,27,28	0.2%	C
Azole antiparasitics1-14,27,28	5%	B
Carbapenems20,21,27,28	NK	C
Caspofungin1-14,27,28	NK	C
Ceftriaxone20,21,27,28	NK	C
Chloramphenicol1-14,20,21,27,28	NK	C
Chloroquine1-14,17,18,27,28	NK	C
Clindamycin1-14,20,21,27,28	NK	C
Cloxacillin/nafcillin1-14,27,28	≤0.01%	C
Cotrimoxazole1-14,17,18,20,21,27,28	NK	C
Dapsone1-14,20,21,27,28	≤1.3%	C
Erythromycin15,20,21,24	NK	C
Ethionamide1-14,26-30	NK	C
Flucloxacillin31	0.0018–0.0036%	C
Flucytosine1-14,20,21,27,28	NK	C

Fluoroquinolones[1-14,23,27,28]	≤0.0001%	C
Fusidic acid[20,21]	NK	C
Griseofulvin[20,21]	NK	C
Hydroxychloroquine[1-14,22,27,28]	NK	C
Isoniazid[1-14,26-30]	1%	B
NNRTIs[1-14,17,18,23,26-29,32]	<15%	B
NRTIs[1-15,20,21,23,30,32,35,45]	<16%	A
Nitrofurantoin[1-14,20,21,27,28]	0.03%	B
Pentamidine[1-14,27,28]	NK	C
Protease inhibitors[1-14,17,18,29,23,26,27,28,32]	<3%	B
Pyrazinamide[1-14,26-30]	NK	C
Ribavirin[1,22]	NK	C
Rifampin[1-14,20,21,26-30]	1.4%	B
Sulfonamides[1-14,20,21,27,28]	NK	C
Telithromycin[1-14,27-29]	NK	C
Terbinafine[1-14,17,18,24,25]	0.02%	C
Tetracyclines[1-18,20,24,25]	NK	B
Thiabendazole[17,18]	NK	C
CARDIOVASCULAR AGENTS		
ACE inhibitors[1-15,20-22]	NK	C
Ajmaline[20,21]	NK	C
Aprindine[20,21]	NK	C
Amiodarone[1-15,17,18,22,26,29]	0.6–3%	B
Angiotensin-receptor blockers[1-15,20-22]	NK	C
β-blockers[1-15,17,18,20,21]	NK	C
Calcium-channel blockers[1-15,17,18,20,21]	NK	C
Disopyramide[15,20,21]	NK	C
Hydralazine[1-15,20,21]	NK	C
Loop diuretics[1-15]	NK	C
Methyldopa[1-15,20,21]	<0.1%	B
Procainamide[15,20,21]	NK	C
Propafenone[15,20,21]	NK	C

Quinidine[1-15,20,21]	2%	B
Spironolactone[1-15]	NK	C
Thiazide diuretics[15,20,21]	NK	C
CHEMOTHERAPEUTIC AGENTS		
Actinomycin[1-14]	NK	C
Aminoglutethimide[20,21]	NK	C
Amsacrine[1-14,20,21]	NK	C
Asparaginase[1-4,17,18]	NK	C
BCNU/CCNU[1-14]	NK	C
Bleomycin[1-14]	NK	C
Bortezomib[29]	NK	C
Busulfan[1-14]	NK	C
Capecitabine[1-14]	NK	C
Carboplatin[1-14]	NK	C
Carmustine[1-14]	NK	C
Chlorambucil[1-14]	NK	C
Cisplatin[1-14]	NK	C
Cyclophosphamide[1-14]	NK	C
Cyclosporine[1-14,20,21,26]	NK	C
Cyproterone acetate[1-14,22]	NK	C
Cytarabine[1-14,20,21]	NK	C
Dacarbazine[1-14]	NK	C
Daunorubicin[1-14]	NK	C
Doxorubicin[1-14]	NK	C
Etoposide[1-14]	NK	C
Floxuridine[20,21]	NK	C
Fluorouracil[29,33]	30–47%	C
Flutamide[1-14,22,29]	NK	C
Gemcitabine[1-14,20,21]	NK	C
Hydroxyurea[1-14]	NK	C
Interleukin-2[20,21]	NK	C
Irinotecan[33]	NK	C

Mercaptopurine[1-14,20,21,23,29]	NK	C
Mitomycin[1-14,17,18]	NK	C
Procarbazine[1-14]	NK	C
Riluzole[1-14,17,18]	NK	C
Streptozocin[1-14]	NK	C
Tamoxifen[17,18,20-22,26]	7%	B
Temozolomide[29]	NK	C
Teniposide[1-14]	NK	C
Thalidomide[22]	NK	C
Thioguanine[1-14,22,26]	NK	C
Thiotepa[1-14]	NK	C
Topotecan[1-14]	NK	C
Toremifene[1-14]	NK	C
Tyrosine kinase inhibitors[29,34]	2%	C
Vinca alkaloids[1-14]	NK	C
ENDOCRINE AGENTS		
Alendronate[29]	NK	C
Androgens[20,21]	NK	C
Carbimazole[22]	NK	C
Corticosteroids[17,18]	NK	C
Cyclofenil[1-14]	NK	C
Danazol[1-14]	NK	C
Estrogens[25,31]	<1%	C
Fenofibrate[1-15,22,26,35]	NK	C
Gemfibrozil[22]	NK	C
Levothyroxine[29]	NK	C
Lomitapide[33]	NK	C
Metformin[1-15,20,21,35]	NK	C
Methimazole[20,21]	NK	C
Mipomersen[33]	NK	C
Niacin[1-15,22,29,35]	NK	C
Orlistat[1-15]	NK	C

Propylthiouracil[1-15,26]	NK	C
Repaglinide[1-15]	NK	C
Sex steroids[17,18,20,21]	0.025%	C
Sibutramine[26]	NK	C
Statins[1-15,20,21,23,27,35,36]	<0.0003%	B
Sulfonylureas[1-15,20,21,35]	NK	C
Thiazolidinediones[1-15,22-24,26,29,35,37]	NK	B
Voglibose[20,21]	NK	C
ENVIRONMENTAL CHEMICALS		
Aflatoxin[1-14,20,21]	NK	C
Allyl compounds[1-14]	NK	C

ACE = angiotensin-converting enzyme, BCNU = bischloroethylnitrosourea, CCNU = 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea, MDMA = 3,4-methylenedioxymethamphetamine, NNRTIs = nonnucleoside reverse-transcriptase inhibitors, NRTI = nucleoside reverse-transcriptase inhibitor, NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

The incidence of drug-induced liver injury (excluding acetaminophen toxicity) has been estimated at 19.1 cases per 100,000 inhabitants per year in a population-based cohort in Iceland. In this population, the injury was caused by a single drug in 75% of the cases (most commonly amoxicillin–clavulanate) and attributed to multiple agents in 9% of cases. Dietary supplements accounted for 16% of all cases of drug-induced hepatic disease. The age-standardized incidence in this population increased dramatically with increasing age.[60] These incidences are likely similar in other populations of European descent.

Hepatotoxicity accounts for approximately 6% of all reported adverse drug reactions, and drug-induced liver injury is responsible for 13% of cases of acute liver failure not caused by acetaminophen toxicity.[59,62] Acetaminophen has been implicated in 39–51% of cases of acute liver failure, and remains a common reason for liver transplantation.[62,63]

Ten percent of cases of acute hepatitis are related to drug toxicity. In patients >50 years of age, 40% of cases of hepatotoxicity are due to medicinal agents. With idiosyncratic drug-induced hepatotoxicity, an individual's particular susceptibility is influenced by both acquired and genetic factors. The risk of hepatotoxicity from drugs ranges from 1 in 10,000 to 1 in 100,000 persons exposed.[59]

Table 38-2 Mechanisms of Drug-Induced Hepatic and Cholestatic Diseases

Predominant Injury	Agents or Class of Agents
HEPATOCELLULAR[1-14,17,18,25,47,50-54]	
Cytotoxic	ACE inhibitors (primarily captopril, enalapril, lisinopril), acetaminophen, actinomycin, adalimumab, aflatoxin (found in foods such as nuts), afluzosin, alendronate, allyl compounds, aloe vera, alverine, amiodarone, amoxicillin, ampicillin, amphetamines (including MDMA), amphotericin (primarily lipid-based), amsacrine, angiotensin-receptor blockers (primarily irbesartan, losartan), azole antifungals (primarily ketoconazole), azole antiparasitics (albendazole, mebendazole, ornidazole), β blockers (primarily propranolol, metoprolol, acebutalol, labetolol), BCNU/CCNU, benzodiazepines, beryllium, black cohosh, bleomycin, bortezomib, bosentan, cade oil, camphor, capecitabine, carbamazepine, carboplatin, carmustine, carp capsules (cyprinol), caspofungin, calcium channel blockers, carbon tetrachloride, cetirizine, chaparral leaf, chaso, chlorambucil, chloramphenicol, chlormethiazole, cisplatin, clindamycin, cloxacillin/nafcillin, clopidogrel, clozapine, cocaine, colchicine, colpachi, cotrimoxazole, cycad nut, cyclofenil, cyclophosphamide, cyclosporine, cyproterone acetate, cytarabine, dacarbazine, danazol, dantrolene, dapsone, desflurane, diclofenac, daunorubicin, dimethylacetaminde, dioxane, disulfiram, doxorubicin, duloxetine, enflurane, ertotinib, etanercept, ethionamide, etodolac, etoposide, etretinate, felbamate, fenofibrate, ferrous salts, flutamide, fluoroquinolones (primarily ciprofloxacin, trovafloxacin), flucytosine, fluorouracil, garlic, gemcitabine, germander, halothane, hexachloroethane, histamine$_2$-receptor antagonists, hydralazine, hydroxychloroquine, hydroxyurea, ibuprofen, imatinib mesylate, indomethacin, infliximab, interferons, isoflurane, isoniazid, jin bu huan (tetrahydropalmatine), kava, lamotrigine, lantana camara, leflunamide, lipokinetix, loop diuretics (primarily furosemide), loratadine, ma huang, monoamine oxidase inhibitors, Mediterranean glue thistle, mercaptopurine, metformin, methyldopa, methylphenidate, minocycline, mistletoe, mitomycin, montelukast, mushroom poisoning, nefazodone, niacin, nimesulide, nitroaliphatic compounds, nitroaromatic compounds, NNRTIs (primarily nevirapine, abacavir), noni, NRTIs (primarily zidovudine, didanosine, stavudine), nitrofurantoin, octreotide, oil of cloves, olanzapine, orlistat, oxaprozin, *para*-aminosalicylic acid, pemoline, pennyroyal oil, pentamidine, pentoxifylline, phencyclidine, phenylbutazone, phenytoin, phosphorus, piroxicam, proton pump inhibitors (primarily omeprazole, rabeprazole), probenecid, procarbazine, propionic

	acid derivatives (bromfenac, fenoprofen, ketoprofen), propylthiouracil, protease inhibitors (primarily ritonavir, indinavir), pyrazinamide, quinidine, repaglinide, rifampin, riluzole, ritodrine, saireito, senna fruit, sevoflurane, shark cartilage, shen-min, sho-saiko-to, sirolimus, spironolactone, SSRIs (primarily fluoxetine, fluvoxamine, sertraline), statins (primarily atorvastatin and simvastatin), streptozocin, sulfasalazine, sulfonamides, sulfonylureas (primarily acetohexamide, gemfibrozil, gliclazide), tacrine, telithromycin, temozolomide, teniposide, terbinafine, terbutaline, teucrium polium, thalidomide, thiazolidinediones (primarily pioglitazone, rosiglitazone, troglitazone), thioguanine, thiotepa, tienilic acid, tolcapone, topiramate, topotecan, trazodone, urethane, valerian root, valproic acid, venlafaxine, vinca alkoloids, zafirlukast
STEATOSIS[1-3,17,18,33,55]	
Microvesicular	Aflatoxin (a contaminant produced by molds), aminosalicylates, amiodarone, antimony antiparasitics, asparaginase, aspirin, camphor, cocaine, didanosine, diltiazem, dimethylformamide, ibuprofen, margosa oil, naproxen, NNRTIs, NRTIs, piroxicam, protease inhibitors (primarily ritonavir and indinavir), riluzole, selenium, sho-saiko-to, tetrabamate, tolmetin, tetracyclines (primarily minocycline), ticlopidine, valproic acid, venencapsan, vinyl chloride, vitamin A, zidovudine
Macrovesicular	Alcohol, amanitin, amiodarone, asparaginase, calcium-channel blockers, carbon tetrachloride, chloroform, chromium, corticosteroids, dichloroethylate, estrogens, ethanol, ethionine, ethyl bromide/chloride, fluorouracil, glucocorticoids, methotrexate, methyl bromide/chloride/dichloride, mitomycin, orotic acid, parenteral lipid, phosphorus, sex steroids, tamoxifen, tannic acid, tetrachloroethylene/trichloroethylene, toremifene, uranium, warfarin, zidovudine
Phospholipidosis	Amantadine, amiodarone, chloroquine, chlorpheneramine, chlorpromazine, cotrimoxazole, cyclizine, fenfluramine, perhexiline maleate, propranolol, sex steroids, tacrine, TCAs, thioridazine, tripelennamine
CHOLESTASIS[20,21,56-58]	
Pure cholestasis	Anabolic steroids, azathioprine, cyclosporine, cytarabine, fosinopril, infliximab, mercaptopurine, sex steroids, tamoxifen
Canalicular	ACE inhibitors (primarily captopril), allopurinol, aminoglutethimide, amoxicillin–clavulanate, anabolic steroids, aniline derivatives, arsenicals, atenolol, azathioprine, barbiturates, carbamazepine, carbapenems, carbimazole, ceftriaxone, chloramphenicol, chlorpropamide, citalopram, clindamycin, cotrimoxazole, cyclosporine, cyproheptadine, cytarabine, diltiazem, disopyramide, flucytosine, fusidic acid, glibenclamide, glipizide, glyburide, gold compounds, griseofulvin, haloperidol, histamine$_2$-receptor antagonists, hydralazine, irbesartan, ketorolac, methyldopa, naproxen, penicillamine, phenytoin, propafenone, propoxyphene, rifampin, risperidone, sex steroids, sho-saiko-to, sulindac, tacrolimus, tricyclic antidepressants, terfenadine, thiazide diuretics, ticlopidine, trazodone, trimethobenzamide, tripelennamine, voglibose
Hepatocanalicular	ACE inhibitors, acetohexamide, amsacrine, azathioprine, β-carotene, carbamazepine, carbimazole, cephalosporins, cascara sagrada, celandine, cetirizine, chaparral leaf, chlorpromazine, clozapine, dapsone, erythromycins (primarily estolate salt), floxuridine, fluphenazine, gabapentin, gemcitabine, gemfibrozil, glimepiride, infliximab, interleukin-2, jin bu huan, linhgzi, loxapine, mercaptopurine, metformin, methimazole, methyldopa, molindone, nitrofurantoin, phenylbutazone, phenytoin, procainamide, prochlorperazine, promazine, quinidine, risperidone, sertraline, statins (primarily cerivastatin, pravastatin), thioridazine, tolazamide, tolbutamide

Cholangiodestructive	Ajmaline, amoxicillin–clavulanate, aprindine, azathioprine, barbiturates, chlorpromazine, chlorpropamide, cimetidine, clindamycin, cotrimoxazole, COX-2 inhibitors (primarily celecoxib), cyproheptadine, flucloxacillin, fluoroquinolones, glibenclamide, glyburide, gold compounds, ibuprofen, mesalamine, nitrofurantoin, paraquot, penicillamine, phenytoin, prochlorperazine, semisynthetic penicillins, sex steroids, sulfonamides, tricyclic antidepressants (primarily amitriptyline, imipramine), terbinafine, tetracycline, thiabendazole, thiazide diuretics, ticlopidine, tiopronin, tolazamide, tolbutamide
VASCULAR[1-14,19,43,50-54]	
Hepatic vein thrombosis	Contraceptive hormones, comfrey, dacarbazine, gordolobo tea, parenteral lipid
Sinusoidal obstruction syndrome (veno-occlusive disease)	Actinomycin, arsenic, azathioprine, busulfan, carmustine, comfrey, cyclophosphamide, cytarabine, dacarbazine, daunorubicin, floxuridine, gordolobo tea, insecticides, mitomycin, nitrosoureas, oxaliplatin, pyrrolizidine alkaloids, skullcap, thioguanine, thorium dioxide, trovafloxacin, urethane, vinca alkaloids, vinyl chloride
Peliosis hepatis	Anabolic steroids, arsenicals, azathioprine, sex steroids, tamoxifen, thioguanine, vitamin A
NEOPLASM[1-3,50-52]	
Benign (adenoma)	Anabolic steroids, antineoplastic agents, octreotide, sex steroids, sassafras
Malignant	Anabolic steroids, sex steroids, vinyl chloride (carcinoma)

ACE = angiotensin-converting enzyme, BCNU = bischloroethylnitrosourea, CCNU = 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea, COX-2 = cyclooxygenase-2 inhibitor, MDMA = 3,4-methylenedioxymethamphetamine, NNRTI = nonnucleoside reverse-transcriptase inhibitor, NRTI = nucleoside reverse-transcriptase inhibitor, SSRI = selective serotonin-reuptake inhibitor.

MECHANISMS

Drug-induced liver injury occurs with a wide range of dosages and lengths of exposure. Resultant injuries may involve one or a combination of the pathologic categories (e.g., a patient can suffer from both hepatocellular and cholestatic disease at the same time). The wide variety of pathological manifestations are a function of the mechanism of hepatotoxicity, the drug itself, amount and duration of exposure, and the inherent susceptibility of the individual taking the drug.[59]

Toxicity from drugs or their metabolites that cause direct damage to cellular components and biochemical processes or elicit immune responses is the foundation for the pathogenesis of the drug-induced liver diseases. The resultant damage and cell death ultimately lead to the clinical manifestation of hepatitis. Injuries are typically categorized by their predominant mechanism: hepatocellular or cytotoxic injury, cholestasis, vascular injury, or neoplasms (Table 38-2).[1-14,17-21,25,33,43,47,50-58] Drugs can cause more than one type of injury, either concurrently or at different points in time.

HEPATOCELLULAR INJURY

Acetaminophen and methotrexate are the most common examples of drugs known to cause direct hepatotoxicity. This injury results from either metabolic derangements or a triggering of an immune response, or, in some cases and to varying degrees, a combination of these. Metabolic injury is typically caused by covalent binding of the drug or its metabolite to intracellular proteins, the mutation of lipid peroxidation by free radicals, the depletion of protective substances such as glutathione, or the loss of ionic gradients and ion homeostasis (particularly calcium). Damage to intracellular structures, organelles, and nuclear DNA can lead to necrosis. Mitochondrial damage and the resultant inability to synthesize ATP can be particularly devastating. The downstream production of reactive oxygen species and free radicals that cause significant oxidative stress by overwhelming antioxidants and other host cell defense mechanisms influence much of this pathogenesis. The subsequent structural and functional damage leads to actin disruption, cell swelling and rupture, and, eventually, cell death.[1,64]

Acetaminophen is responsible for 39–51% of all acute liver failure cases.[62] It is predominantly metabolized by glucuronidation and sulfation, with approximately 10% being converted to the reactive metabolite *N*-acetyl-*p*-benzoquinone imine (NAPQI) via the CYP enzyme system. NAPQI is responsible for acetaminophen-associated hepatotoxicity. This metabolite is formed by CYP2E1 through a direct two-electron oxidation of acetaminophen and is rapidly detoxified by glutathione when acetaminophen is ingested in typical therapeutic amounts.[65] Glutathione is an antioxidant that protects important cellular components from damage caused by reactive oxygen species such as free radicals. When too much acetaminophen is ingested (e.g., from intentional or unintentional overdose), the sulfation and glucuronidation pathway becomes saturated, resulting in a shunting to the CYP system and the production of large amounts of NAPQI, which binds and depletes liver reserves of glutathione.[66] NAPQI is toxic to cellular components if not detoxified by conjugation with glutathione. NAPQI reacts with protein sulfhydryl groups in the hepatocyte mitochondria. Resultant mitochondrial damage includes collapse of the membrane potential (mediated by triggering the opening of the mitochondrial permeability transition pore), release of endonuclease G and apoptosis-inducing factor (both of which translocate to the cell nucleus and cause extensive DNA fragmentation), and inhibition of ATP synthesis.[66-68]

Mitochondrial oxidative stress from NAPQI results in the production of superoxide anion and subsequently peroxynitrite (both of which are deleterious to many intracellular components, particularly DNA and proteins). Peroxynitrite can also inactivate superoxide dismutase 2 (a process normally blocked by glutathione). These processes lead to further production of reactive oxygen species which in turn activates the redox-sensitive mitogen-activated protein kinase c-Jun N-terminal kinase 1/2, which translocates into the mitochondria, thereby creating an amplification loop that further increases mitochondrial oxidative stress. Translocation of mitochondrial proteins such as apoptosis-inducing factor and endonuclease G into the nucleus results in DNA fragmentation and oncotic necrosis.[68] Recent research has described the role of additional kinases such as receptor-interacting protein kinases 1 and 3 in promoting hepatocellular mitochondrial fission and oxidant stress.[66] The combination of mitochondrial damage and nuclear disintegration ultimately leads to widespread hepatocellular necrosis. In fact, all signaling pathways ultimately result in cellular necrosis.[66] Apoptosis is no longer considered to be a relevant mechanism of acetaminophen-associated hepatotoxicity.[69] Further investigation is needed to determine the role of inflammatory mediators, the innate immune system, Kupffer cells, non-Kupffer cells, neutrophils, and macrophages in the development and propagation of hepatocellular injury related to acetaminophen overdose.[65]

Immune-mediated hepatotoxicity is another form of direct liver injury but compared with the dose-dependent cytotoxicity tends to be idiosyncratic in nature. Idiosyncratic drug-induced liver disease is most commonly immune-mediated. The inherently unpredictable nature of idiosyncratic reactions poses a particular challenge to the clinician. Largely related to individual susceptibility, these reactions vary widely in latency, presentation, and course. This form of drug-induced liver injury involves sensitization of hepatocytes to cytokines by way of haptenization (covalent binding of the drug or metabolite to a cellular protein). This promotes the formation of antigen-recognizing helper and cytotoxic T cells via the major histocompatibility complex type II. Interaction with major histocompatibility complex type I leads to activation of humoral and cellular immune responses. Damage to hepatocytes leads to cell destruction and apoptosis.[3]

Examples of identified antibodies include antiliver/kidney microsomal antibody that specifically targets CYP2C9 of the liver and kidney; antiliver microsomal antibody (e.g., as induced by carbamazepine) that targets CYP1A2, an isoenzyme not found in the kidney; antimitochondrial antibody (e.g., as induced by isoniazid); antimicrosomal epoxide hydrolase (e.g., as induced by germander); anti-CYP 1A2 (e.g., as induced by hydralazine); and anti-CYP 2E1 (e.g., as induced by halothane). The inflammatory reaction is mediated by inflammatory cytokines, including interleukin-1, tumor necrosis factor (TNF), nitric oxide, and interferon.[13,50-54,70-73]

Hepatic steatosis is histologically defined as a deposition of triglycerides within the hepatocyte. Intrahepatocyte triglycerides are the product of glycerol and free fatty acid metabolism, and inappropriate accumulation is usually due to increased uptake from peripheral tissue or dietary sources, increased de novo lipogenesis within the hepatocyte, reduced utilization (β-oxidation), or reduced elimination (export of triglyceride in the form of very-low-density lipoprotein [VLDL]). Steatohepatitis is steatosis accompanied by inflammation and hepatocyte injury (ballooning), with or without fibrosis.[55,74]

Drug-induced steatosis is further categorized by the predominant steatotic feature: macrovesicular steatosis (peripheral displacement of the cell nucleus), microvesicular steatosis, and steatohepatitis.[75] Some drugs (e.g., tamoxifen and amiodarone) can accumulate in the mitochondria of hepatocytes. This accumulation can interfere with the mitochondrial electron transport chain and β-oxidation. Blocking the flow of electrons through the electron transport chain leads to an accumulation of electrons that can directly interact with oxygen to promote the formation of reactive oxygen species. This, along with ATP depletion and inflammation, ultimately result in cellular necrosis.[55] Other medications (e.g., troglitazone and salicylate) inhibit the entry of long-chain fatty acids into the mitochondrial matrix, leading to their accumulation in the cytosol and subsequent conversion (esterification) into triglycerides. This by itself can lead to triglyceride accumulation within the hepatocyte, while other drugs (e.g., tetracycline) inhibit the export and transport of triglycerides as VLDL.[55]

If the drug-induced steatosis does not progress to steatohepatitis or cirrhosis, it is generally reversible. Some individuals may be more susceptible to drug-induced hepatic steatosis due to risk factors (e.g., obesity and metabolic syndrome), comorbidities, or genetic predisposition. Steatosis may increase the liver's vulnerability to injury, particularly from other drugs known to interfere with mitochondrial function. Because steatosis associated with nonalcoholic fatty liver disease is becoming increasingly prevalent in Western populations, there is concern that consumption of drugs with the potential for inducing steatosis could increase risk for progression to steatohepatitis. A steatotic liver may also lead to impairment of CYP enzymatic function and altered metabolism of substrates.[33,55]

Other mechanisms that appear to play a role in drug-induced hepatic steatosis and are being investigated include increased expression levels of fatty acid translocase via increased peroxisome proliferator-activated receptor alpha, increased expression of sterol regulatory element-binding protein-1c, and decreased adenosine monophosphate-activated protein kinase.[33]

CHOLESTATIC INJURY

Cholestasis is defined clinically as stagnant bile or the failure of bile to reach the small intestine and is the result of impaired bile acid secretion by hepatocytes or obstruction of bile flow through intra- or extrahepatic bile ducts.[31] Drug-induced hepatocholestasis tends to be an idiosyncratic reaction and is classified as either acute or chronic. Acute hepatocholestasis is more common and occurs primarily as a result of alterations in bile secretion into the canaliculus. This can occur either with hepatocellular injury and inflammation or without (known as bland cholestasis). Injury to the hepatocyte is caused by an accumulation of bile acids within the cell causing mitochondrial damage and ultimately resulting in apoptosis and necrosis.[76] After some drugs (e.g., cyclosporine) are detoxified via Phase 1 and II reactions in the hepatocyte, their metabolites are transported (effluxed) into hepatic canaliculi for biliary excretion. Canalicular transporters, known as multidrug-resistance proteins, facilitate the efflux of bile acids from the hepatocyte into the canaliculus. Drugs and metabolites that induce hepatocholestasis by disrupting bile acid homeostasis typically do so via inhibition of bile acid transport across the canalicular membrane (the rate-limiting step in bile formation). This disruption occurs either through the direct inhibition of transport proteins, indirectly, through internalization and degradation of the transporter protein, or through altered gene expression for these proteins. The bile salt export pump (BSEP) is thought to be the most common transporter inhibited by drugs that induce hepatocholestasis, particularly in individuals with the V444A polymorphism of BSEP.[31]

Chronic hepatocholestasis is a result of direct injury to the bile ducts or ductules (vanishing bile duct syndrome) and can occur more than 6 months after the initial cholestatic insult. It can also appear as sclerosing cholangitis. Direct injury to bile ductular cells is a result of exposure to the offending drug or metabolite during canalicular excretion, either by direct toxic effects or immune sensitizing effects.[10]

VASCULAR INJURY

Certain drugs (particularly antineoplastics) can cause injury to hepatic stellate cells and endothelial cells lining the hepatic sinusoids. This results in endothelial swelling and thrombosis within the small hepatic venules, leading to venous outflow obstruction (due to luminal occlusion), sinusoidal dilatation, congestion, hepatocellular necrosis, and possibly centrilobular fibrosis. This condition is known as sinusoidal obstruction syndrome, or veno-occlusive disease. Other drugs can cause the development of peliosis hepatis, in which the hepatic parenchyma develops multiple blood-filled cavities without an endothelial lining. This is hypothesized to result from either sinusoidal endothelial cell injury, increased sinusoidal pressure due to blood outflow obstruction, or hepatocellular necrosis. Rupture of these blood-filled cavities can result in severe peritoneal hemorrhage.[43]

A rare drug-induced vascular abnormality is hepatic vein thrombosis, which occludes the hepatic vein and presents clinically as Budd–Chiari syndrome. Injury to endothelial cells of both sinusoids and small hepatic venules activates the coagulation cascade and formation of a thrombus. This thrombosis then occludes the hepatic vein, leading to increased portal vein and hepatic sinusoid pressures and the formation of ascites and esophageal varices.[43,77]

NEOPLASTIC INJURY

Neoplastic lesions of the liver such as focal nodular hyperplasia, hepatocellular adenoma, hepatocellular carcinoma, and angiosarcoma have been linked to several drugs. Most neoplasms are benign and are typically associated with prolonged exposure. The pathologic mechanisms explaining drug-induced liver neoplasms have not been fully elucidated, but are likely related to alterations in DNA.[43,78]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

There are no standard diagnostic criteria for drug-induced liver injury, and a diagnosis is typically one of exclusion. Diagnosis is a challenge due to lack of standardized diagnostic criteria, broad heterogeneity of clinical presentation, delays in patient presentation, and difficulty in determining a specific culprit in cases of polypharmacy. The diagnosis of drug-induced liver injury is often based on clinical suspicion and how well the symptoms and signs correlate with information from similar case reports. This emphasizes the importance of obtaining a thorough medication history including use of prescription and nonprescription drugs as well as exposure to recreational drugs, dietary supplements, herbal and natural products, alternative and complimentary therapies, chemicals, and toxins. Integrating the exposure history, the dose and duration of use of the suspected agent, presenting signs and symptoms, and pathologic and histologic patterns is paramount in formulating a diagnosis.

To assist with the diagnostic differentiation between the major types of drug-induced liver disease, a method using biochemical patterns has been described. It determines the ratio of alanine aminotransferase (ALT) to alkaline phosphatase (ALP) relative to their respective upper limits of normal (ULN). The R (ratio) value is calculated according to the formula R = ALT/ULN ÷ ALP/ULN. An R value ≥5 indicates hepatocellular liver injury, and a value ≤2 indicates cholestatic injury. Values between 2 and 5 characterize the mixed form of drug-induced liver injury.[31,79-81] **Table 38-3** presents the typical biochemical patterns observed with each mechanistic category of drug-induced liver disease.[1-14,17,18,21,56,82-86]

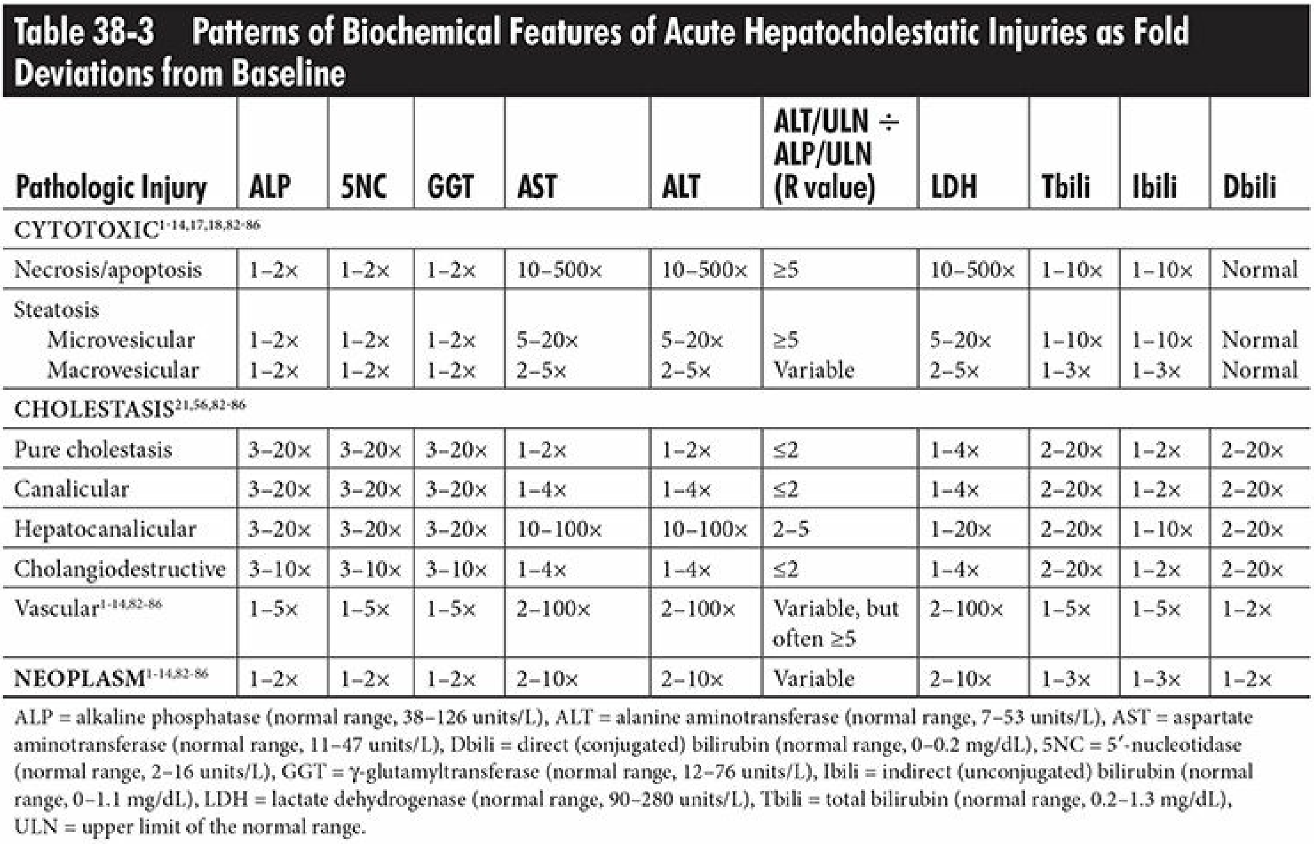

Table 38-3 Patterns of Biochemical Features of Acute Hepatocholestatic Injuries as Fold Deviations from Baseline

Pathologic Injury	ALP	5NC	GGT	AST	ALT	ALT/ULN ÷ ALP/ULN (R value)	LDH	Tbili	Ibili	Dbili
CYTOTOXIC[1-14,17,18,82-86]										
Necrosis/apoptosis	1–2×	1–2×	1–2×	10–500×	10–500×	≥5	10–500×	1–10×	1–10×	Normal
Steatosis										
Microvesicular	1–2×	1–2×	1–2×	5–20×	5–20×	≥5	5–20×	1–10×	1–10×	Normal
Macrovesicular	1–2×	1–2×	1–2×	2–5×	2–5×	Variable	2–5×	1–3×	1–3×	Normal
CHOLESTASIS[21,56,82-86]										
Pure cholestasis	3–20×	3–20×	3–20×	1–2×	1–2×	≤2	1–4×	2–20×	1–2×	2–20×
Canalicular	3–20×	3–20×	3–20×	1–4×	1–4×	≤2	1–4×	2–20×	1–2×	2–20×
Hepatocanalicular	3–20×	3–20×	3–20×	10–100×	10–100×	2–5	1–20×	2–20×	1–10×	2–20×
Cholangiodestructive	3–10×	3–10×	3–10×	1–4×	1–4×	≤2	1–4×	2–20×	1–2×	2–20×
Vascular[1-14,82-86]	1–5×	1–5×	1–5×	2–100×	2–100×	Variable, but often ≥5	2–100×	1–5×	1–5×	1–2×

ALP = alkaline phosphatase (normal range, 38–126 units/L), ALT = alanine aminotransferase (normal range, 7–53 units/L), AST = aspartate aminotransferase (normal range, 11–47 units/L), Dbili = direct (conjugated) bilirubin (normal range, 0–0.2 mg/dL), 5NC = 5′-nucleotidase (normal range, 2–16 units/L), GGT = γ-glutamyltransferase (normal range, 12–76 units/L), Ibili = indirect (unconjugated) bilirubin (normal range, 0–1.1 mg/dL), LDH = lactate dehydrogenase (normal range, 90–280 units/L), Tbili = total bilirubin (normal range, 0.2–1.3 mg/dL), ULN = upper limit of the normal range.

Several scales and algorithms have been developed to help assess causality in cases of suspected drug-induced liver injury. The most widely used scale is the Roussel Uclaf Causality Assessment Method (RUCAM).[80,81] This method assigns a categorical likelihood of causality to a given drug and liver injury situation. It incorporates data from seven domains: (1) time to onset of the injury after initiation of the suspected agent, (2) progression and course of the reaction after suspected drug discontinuation, (3) risk factors, (4) concomitant drugs, (5) nondrug causes of liver injury, (6) previous information on the hepatotoxic potential of the drug, and (7) response to rechallenge. The RUCAM scale has demonstrated 86% sensitivity, 89% specificity, and positive and negative predictive values of 93% and 78%, respectively. The likelihood categories determined are highly probable, probable, possible, unlikely, and excluded.[80,81] **Table 38-4** provides situations in which a drug or other xenobiotic could be a likely cause of liver injury.[1-58,82-86]

Table 38-4 Situations Indicating Xenobiotics as a Likely Cause of Hepatocholestatic Disease[1-58,82-86]

- Abnormal results on liver tests in complex medical situations
- Acute hepatitis or cholestasis not readily accounted for by other causes, such as viruses, other infections, gallstones, alcohol, metabolic or immunologic disorders
- Atypical features of liver disease are present, such as mixed hepatocholestatic injury or microvesicular steatosis
- Cholestasis with normal bile duct caliber on imaging

- Chronic hepatitis without autoantibodies or hyperglobulinemia
- Histologic features representative of drug-induced hepatic injury (see text)
- Indication by a questionnaire or algorithm designed to determine likelihood of an adverse effect (e.g., Naranjo Scale >8)
- Obscure or poorly explained liver disease among those taking long-term steroids (anabolic or sex steroids), immunosuppressive agents, or other drugs (including dietary supplements)
- Presence of extrahepatic manifestations, especially rash, lymphadenopathy, eosinophilia
- The patient has recently started a new medication or dietary supplement

Patients experiencing drug-induced liver injury usually present with either hepatitis-like symptoms (nausea, vomiting, lethargy, jaundice, abdominal discomfort, pruritus) or elevated liver enzymes. Most cases of drug-induced liver disease occur within 1 week to 3 months following initial exposure to the agent.[2] **Table 38-5** provides a detailed list of signs and symptoms that have been associated with drug-induced hepatocholestatic diseases.[1-14,17-21,31,56,60]

Table 38-5 Signs and Symptoms Associated with Hepatic and Cholestatic Diseases[1-14,17-21,31,56,60]

- Abdominal pain
- Anemia
- Anorexia, weight loss, fatigue, malaise
- Ascites
- Asterixis
- Caput medusae
- Coagulopathy
- Decreased albumin
- Encephalopathy
- Eosinophilia
- Epigastric valvular murmur (Cruveilhier–Baumgarten syndrome)
- Fetor hepaticus (sweet-pungent smell on breath)
- Fever
- Finger clubbing
- Gynecomastia, loss of hair in males
- Hepatomegaly
- Hepatopulmonary syndrome
- Hepatorenal syndrome
- Hypoglycemia or hyperglycemia
- Hypogonadism
- Hyponatremia
- Increased 5′-nucleotidase
- Increased ALP/GGT
- Increased AST/ALT
- Increased bilirubin
- Jaundice
- Lactic acidosis
- Nodular liver
- Palmar erythema

- Presence of autoimmune serum markers (e.g., antinuclear antibody, antismooth muscle antibody, lupus erythematosus, antimitochondrial antibody)
- Presence of liver-specific antibodies (e.g., LKM, LM)
- Pruritus
- Rash
- Scleral icterus
- Spider angioma
- Splenomegaly
- Steatorrhea
- Thrombocytopenia and leukopenia
- Varices
- Weight gain
- White nails

ALP = alkaline phosphatase, ALT = alanine aminotransferase, AST = aspartate aminotransferase, GGT = γ-glutamyl transferase, LKM = antiliver/kidney microsomal antibody, LM = antiliver microsomal antibody.

Drug-induced hepatic injury mimics many other liver disorders, making diagnosis challenging. It can be difficult to distinguish the clinical presentation from viral hepatitis, cholangitis, and autoimmune hepatitis. This underscores the importance of obtaining a detailed history of the presenting illness, recent travel, therapeutic drug and dietary supplement use, and illicit drug use.[31] **Table 38-6** lists the various conditions to consider in the differential diagnosis of drug-induced liver disease.[1-14,17,18,20,21,56] **Table 38-7** describes extrahepatic syndromes associated with drug-induced hepatocholestatic diseases.[1-14,17,18,20,21,56]

Table 38-6 Conditions to Consider in the Differential Diagnosis of Drug-Induced Hepatic and Cholestatic Diseases[1-14,17,18,20,21,56]

Cytotoxic pattern of damage

- Autoimmune disorders
- Epstein–Barr virus
- Heat stroke
- Ischemic liver
- Leukemia/lymphoma
- Neoplasms
- Pregnancy
- Reye syndrome
- Sea anemone stings
- Trauma
- Varicella zoster
- Viral hepatitis
- Wilson disease

Cholestasic pattern of damage

- Acquired immunodeficiency syndrome
- Allograft rejection

- Autoimmune cholangiopathic disorders
- Bacterial infections
- Bile duct strictures
- Biliary atresia
- Cholangitis
- Cholecystitis
- Cholestatic liver disease
- Congenital abnormalities (e.g. porphyrias, Byler syndrome, α_1-antitrypsin deficiency)
- Cystic fibrosis
- Graft-versus-host disease
- Lymph node compression (lymphoma)
- Neoplasms
- Pancreatitis
- Portal vein thrombosis
- Postoperative cholestasis
- Viral hepatitis

Vascular damage

- Behçet disease
- Budd–Chiari syndrome
- Cirrhosis
- Collagen vascular diseases
- Constrictive pericarditis
- Hypercoagulation states
- Infections
- Inflammatory bowel disease
- Myeloproliferative disorders, sarcoidosis
- Polycystic liver disease
- Pregnancy
- Systemic lupus erythematosus
- Total-body irradiation
- Trauma

Neoplasm formation

- Metastatic neoplasms
- Primary neoplasm of liver, pancreas, gastrointestinal tract

Table 38-7 Extrahepatic Syndromes Associated with Drug-Induced Hepatic and Cholestatic Diseases[1-14,17,18,20,21,56]

Drug	Syndrome
Amoxicillin–clavulanate, chlorpromazine, erythromycin estolate	Obstructive jaundice
Anticonvulsants, chloramphenicol, gold salts, propylthiouracil, phenylbutazone	Associated bone marrow injury
Carbamazepine, phenytoin	Fever, rash, atypical lymphocytosis, lymphadenopathy
Clofibrate	Mylagias, stiffness, weakness, elevated creatine kinase

Dapsone	Fever, jaundice, rash, anemia (sulfone syndrome)
Dapsone, carbamazepine, minocycline, phenytoin, sulfonamides	Fever, rash, perspiration, lymphadenopathy (mononucleosis syndrome)
Gold salts, methoxyflurane, paraquat, penicillamine	Associated renal injury
Intravenous tetracycline, valproic acid Methyldopa, oxyphenisatin	Anorexia, nausea, vomiting, somnolence, encephalopathy resembling fatty liver of pregnancy Autoimmune hemolysis
Nitrofurantoin, amiodarone Phenytoin, *para*-aminosalicylate, sulfonamides	Associated pulmonary injury Fever, rash, lymphadenopathy, arthralgias (serum sickness syndrome)

HEPATOCELLULAR INJURY

Signs and symptoms of hepatocellular injury can occur within days after exposure but most commonly (with the exception of acetaminophen) take a week or more to develop. The clinical presentation typically includes malaise, abdominal pain, and jaundice. These findings along with coagulopathy (indicated by an elevated prothrombin time or international normalized ratio [INR]) and encephalopathy indicate particularly severe liver injury.[4] Marked elevations in ALT and aspartate aminotransferase (AST), usually preceding increases in total bilirubin levels, and only modest increases in ALP are characteristic of hepatocyte damage. Immune-mediated cytotoxicity is frequently associated with fever, rash, arthralgia, and eosinophilia.

Drug-induced hepatic steatosis is usually asymptomatic, so diagnosis is often delayed. The disorder may be discovered when liver enzymes are measured as part of routine screening or work-up for an unrelated medical problem and found to be elevated. Fatigue and right upper quadrant discomfort may be the only presenting symptoms. Patients with steatohepatitis may report abdominal fullness or discomfort. If the disease is more severe, patients may present with nausea, vomiting, steatorrhea, abdominal pain, pruritus, and fatigue. ALT increases are variable. Histologic examination can provide a definitive diagnosis of steatosis and steatohepatitis, but even then, establishing causality with a specific drug is challenging.[43,55,75]

CHOLESTATIC INJURY

Drug-induced cholestatic injury is typically seen within 4 weeks following drug initiation but can also occur even after the drug has been discontinued. Although the clinical presentation is nonspecific and variable, it is commonly characterized by jaundice and pruritus. Additional signs and symptoms may include fatigue, malaise, anorexia, and nausea. Patients may also be asymptomatic. For a diagnosis of cholestatic injury, patients must have an ALP greater than twice the ULN and/or an R value of less than 2. ALP elevations usually precede increases in ALT. Elevations of gamma-glutamyl transferase have also been observed. Fever and rash are characteristic of drug-induced hypersensitivity reactions.[31] Most acute cases resolve shortly after discontinuation of the offending agent. Patients with chronic cholestasis initially present with elevated ALP and jaundice, which can sometimes last several months to years. These patients can also experience protracted pruritus and fatigue and may develop xanthomas. Although uncommon, pain may occur with intrahepatic cholestasis and can mimic that associated with acute cholecystitis, cholangitis, or choledocholithiasis.[31]

VASCULAR INJURY

Sinusoidal obstruction syndrome usually manifests within 1–3 weeks following initial drug exposure, but a chronic form of this disorder can present months to years afterward. Presenting signs and symptoms typically include some combination of rapid weight gain, ascites, jaundice, right upper-quadrant pain, portal hypertension (as evidenced by varices, ascites, and edema and occasionally encephalopathy, muscle wasting, and weakness), and varying degrees of ALT and AST elevation. The histologic pattern reflects sinusoid obstruction in central areas with hepatocyte necrosis and hemorrhage.[19]

The clinical presentation of other drug-induced hepatic vascular injuries, such as peliosis hepatis (a rare condition of multiple blood-filled cavities throughout the liver), are nonspecific and can include epigastric pain and nausea. It is not uncommon for these injuries to be found as incidental findings on abdominal imaging.[87] Hepatic vein thrombosis presents clinically as Budd–Chiari syndrome, featuring hepatomegaly, abdominal pain, and ascites.[77]

NEOPLASTIC INJURY

Drug-induced hepatic neoplasms may be benign or malignant. The most common signs and symptoms include fatigue, anorexia and weight loss, presence of a palpable mass, and abdominal pain or discomfort.

RISK FACTORS

Table 38-8 lists the various risk factors (and examples of associated medications) for drug-induced hepatic and cholestatic diseases.[34,59,85,88-91] Both nonmodifiable (genetic predisposition, sex, age) and modifiable (alcohol consumption, malnutrition, medications) factors play important roles in drug-induced liver disease. Drug-induced hepatic injuries are sometimes reasonably predictable. For example, hepatic injury might be expected following a large single dose of acetaminophen or excessive cumulative doses of amiodarone or methotrexate. Also, patients with chronic viral infections (e.g., human immunodeficiency virus) may be predisposed to immune-mediated cytotoxicity from some medications (e.g., isoniazid).[50-54] Illicit drug use, including cocaine and 3,4-methylenedioxymethamphetamine ("Ecstasy"), are directly linked to fulminant hepatic failure. Psilocybin mushrooms (used illicitly) usually cause hepatotoxicity only upon repeated use, whereas ingestion of toxic (poisonous) mushrooms can lead to fulminant hepatic failure. Pharmacokinetic or pharmacodynamic interactions may enhance susceptibility to idiosyncratic hepatocholestatic injuries. Exposure to some foods and chemical agents associated with construction, agriculture, horticulture, printing, plastic fabrication, plumbing, dry cleaning, and laboratory techniques may independently produce hepatic dysfunction.[59,86]

Table 38-8 Risk Factors for Drug-Induced Hepatic and Cholestatic Diseases[34,59,85,88-91,a]

Factor	Medications
Age	
Older	Acetaminophen, amoxicillin–clavulanate, isoniazid, halothane, nitrofurantoin, troglitazone
Younger	Erythromycin, salicylates, valproic acid
Gender	
Male	Amoxicillin–clavulanate, azathioprine
Female	Diclofenac, halothane, isoniazid, methyldopa, minocycline, nitrofurantoin, sulindac, propoxyphene, erythromycin
Obesity	Halothane, methotrexate, tamoxifen
Diabetes mellitus	Methotrexate
Autoimmune/Immune-mediated disorders	Salicylates, TNFα inhibitors, azathioprine, 6-mercaptopurine
Pregnancy	Acetaminophen, isoniazid, tetracycline
Renal dysfunction	Allopurinol, intravenous tetracycline, methotrexate
Cancer chemotherapy	Tyrosine kinase inhibitors, interleukin 2, monoclonal antibodies, cisplatin, oxaliplatin, etoposide, vinca alkaloids, doxorubicin, daunorubicin, azathioprine, fluorodeoxyuridine, thioguanine, 6-mercaptopurine
Dyslipidemia	Statins, niacin
Acquired immune deficiency syndrome	Trimethoprim–sulfamethozazole, dapsone, isoniazid

Underlying liver disease	
Chronic hepatitis B or C	Flutamide, ibuprofen, isoniazid, ritonavir, methotrexate
Nonalcoholic fatty liver disease	Steroids, methotrexate, tamoxifen, tetracycline, irinotecan, nucleoside reverse transcriptase inhibitors
Fasting, malnutrition	Acetaminophen, methimazole, rifampin
Alcohol consumption	Acetaminophen, halothane, isoniazid, methotrexate, vitamin A
Cumulative dose	Amiodarone, bromfenac, methotrexate, oral contraceptives
Increased dose	Acarbose, acetaminophen, cocaine, cyclophosphamide, cyclosporine, methotrexate, niacin, perhexiline, phencyclidine, salicylates, tacrine, tetracycline, valproic acid, vitamin A
Pharmacokinetic interaction	Phenobarbital or phenytoin enhances valproic acid toxicity; isoniazid enhances acetaminophen toxicity
Pharmacodynamic interaction	Pyrazinamide or isoniazid enhances rifampin toxicity; acetaminophen and pennyroyal oil enhance toxicity of one another; valproic acid and chlorpromazine enhance toxicity of one another; isoniazid, zidovudine, cotrimoxazole, phenytoin, carbamazepine, barbiturates enhance acetaminophen toxicity
Genetic predisposition	
CYP2C19 deficiency	Phenobarbital carbonate derivatives
CYP2E1 or CYP1A2 deficiency	Isoniazid, sulfonamides
N-acetyltransferase 2 deficiency	Hydralazine, isoniazid, sulfonamides
Sulfoxidation deficiency	Chlorpromazine
Epoxide hydrolase inhibition or deficiency	Carbamazepine, halothane, phenobarbital, phenytoin
Glutathione synthetase or transferase deficiency	Acetaminophen, tacrine, troglitazone, amoxicillin–clavulanate
Glucuronosyl transferase deficiency	Diclofenac, tolcapone
Human leukocyte antigen allele association	Antituberculosis medications, carbamazepine, amoxicillin-clavulanate, nevirapine, lapatinib, lumiracoxib, ticlopidine
Manganese superoxide dismutase variation	Antituberculosis medications
ATP-binding cassette transporter association	Diclofenac, nevirapine

ATP = adenosine triphosphate, CYP = cytochrome P450 enzyme system, TNF = tumor necrosis factor.

[a] The National Institutes of Health provides a repository of information on herbal and dietary supplements associated with drug-induced liver injury (http://www.livertox.nih.gov).[49]

Although some evidence exists for cross-sensitivity between medications within a given class, there are only a few concrete examples, including the antiepileptics (phenytoin and carbamazepine), inhaled anesthetics (isoflurane, halothane, and enflurane), and the histamine$_2$-receptor antagonists.[59,86]

Growing evidence suggests that high daily dose, regardless of the medication itself, is associated with increased mortality and should be considered a modifiable risk factor.[34] As an example, the use of oral contraceptives has been described as a cumulative dose-dependent risk factor for veno-occlusive hepatic dysfunction.

In general, patients with mild-to-moderate chronic liver disease are not at increased risk of idiosyncratic drug-induced liver diseases.[1-3] Exceptions include patients who receive methotrexate, tolcapone, pemoline, or niacin. Patients with severe liver disease or cirrhosis have altered pharmacokinetic profiles (absorption, metabolism, volume of distribution) increasing the risk of drug-induced liver injury. Injury may not ensue, however, because several enzyme systems, particularly Phase 2 conjugation reactions, are often preserved. Patients with diabetes, obesity, or hyperlipidemia are at increased risk of steatohepatitis, which may increase the susceptibility to various types of liver injury.[17,18,92] It is prudent to consider dose adjustment for any medication implicated in drug-induced hepatic and cholestatic diseases (Table 38-1) based on severity of liver disease.[93]

The study of genetic variations on drug-induced liver injury has led to the conclusion that liver injury due to medication varies by genetic susceptibility. Further work in this field may have lasting impact on the incidence of drug-induced liver injury.

An understanding of the risk factors associated with acetaminophen toxicity provides insight into the complexities of drug-induced liver disease. As noted above, approximately 10% of ingested acetaminophen undergoes biotransformation to the toxic metabolite NAPQI, which, under normal circumstances, is immediately inactivated by conjugation with glutathione. CYP2E1 is the enzyme primarily responsible for the production of NAPQI; therefore, increasing CYP2E1 activity can increase concentrations of NAPQI, as is the case with chronic alcohol ingestion, which results in a twofold increase in CYP2E1 concentrations.[50,51,53] In addition to enzymatic impact on NAPQI production, concomitant medications can significantly impact the CYP system. Inducers of bioactivating enzymes of acetaminophen may increase the acetaminophen bioactive dose and, therefore, toxicity. For example, tobacco use is an independent risk factor for mortality following acetaminophen exposure, presumably because tobacco smoke contains inducers of CYP1A2.[50,51,53] Isoniazid induces CYP2E1 and antiepileptics (phenytoin, carbamazepine, barbiturates) induce CYP3A4, which may lead to an increase in acetaminophen and NAPQI concentrations. Individuals treated with zidovudine for human immunodeficiency virus infection or co-trimoxazole for urinary tract or skin and soft tissue infection may have increased acetaminophen toxicity due to shunting more of the drug to the CYP system from competitive inhibition for glucuronyl transferase.[50,51,53] Poor nutritional status contributes to diminished glucuronidation, induction of CYP2E1, and glutathione depletion, possibly enhancing acetaminophen toxicity. And, finally, the existence of genetic polymorphisms may influence the metabolism of acetaminophen and alter the risk of toxicity.[50,51,53] In summary, risk assessment of drug-induced liver disease is complex and typically multifactorial.

MORBIDITY AND MORTALITY

The majority of patients with drug-induced hepatic injury will completely recover after removal of the offending medication. However, this drug-induced disease accounts for 2–3% of all hospital admissions and only 20–25% of patients with acute idiosyncratic fulminant hepatic failure survive 3 weeks without liver transplantation.[62,94] The most likely causes of death in these patients include cerebral edema, sepsis, multiorgan failure, cardiac arrhythmia/arrest, and respiratory failure.[62] Although mild-to-moderate liver dysfunction can cause significant morbidity (Table 38-5), mortality is not common.[1-14,17,18,20,21,56] Factors related to an increased risk for mortality include pre-existing liver disease; elevated serum creatinine or the need for hemodialysis; jaundice (bilirubin >2× ULN) with aminotransferase concentrations >3× ULN (Hy's Law); occurrence in childhood (particularly in children taking antiepileptic drugs); and higher daily medication doses.[34,95-98] In general, extended exposure to the hepatotoxin will also worsen the prognosis. Jaundice can persist for several months after resolution of acute liver injury. Elevated AST or bilirubin, female sex, and increased age are associated with higher mortality in patients who experience hepatocellular reactions, whereas only elevated bilirubin is predictive of mortality in patients with cholestatic injuries.[96-98]

PREVENTION

Table 38-9 lists approaches to help prevent drug-induced hepatic and cholestatic diseases.[1-9,94,99] Early recognition of signs and symptoms of hepatic injury and rapid discontinuation of the causative agent are the best approaches to prevent serious sequelae. Patients with known risk factors should not receive hepatotoxic agents if alternative treatment methods are available. Manufacturers of some medications with known hepatotoxic potential provide specific recommendations for biochemical monitoring that can be followed and some professional organizations have published guidelines for monitoring use of potential hepatotoxins. For medications known to induce serious liver injury in 1–2% of exposures, monthly biochemical monitoring may be cost-effective. This has not been found to be true, however, for medications that are less frequently associated with severe drug-induced liver disease.[59]

Table 38-9 Approaches to Help Prevent Drug-Induced Hepatic and Cholestatic Diseases[1-9,94,99]

Global

- Postmarketing surveillance and reporting
- Preclinical drug testing in animals
- Restricted availability (e.g., blister packaging of nonprescription medication)
- Serial biochemical assessment during clinical studies

Patient-specific

- Adherence to dosing guidelines
- Appropriate patient education on the medication expectations and signs/symptoms of hepatic injury (Table 38-5)
- Appropriate use of the medication
- Avoid polypharmacy and herbal medicines
- Avoid use of agents in patients with known risk factors (Table 38-8)
- Control other disease states (e.g., hyperthyroidism, diabetes mellitus, and hyperlipidemia)
- Genomic testing for potential susceptibility, if applicable/suspected
- Maintain nutrition
- Minimize alcohol consumption, occupational exposures, and illicit drug use
- Rapid recognition of injury and associated extrahepatic syndromes (Table 38-7)
- Serial biochemical monitoring in high-risk patients or with agents known to cause injury

MANAGEMENT

Most cases of drug-induced hepatocholestatic dysfunction can be treated by discontinuing the offending medication. In general, discontinuation results in rapid reversal of signs and symptoms if the injury is mild-to-moderate. A 50% reduction of hepatic-associated serum enzymes can be expected within 1 week if the injury is hepatocellular, but this degree of improvement may take 6 months or longer if the injury is cholestatic.[1-14,16,17,20,21,56,96-98] Recovery following discontinuation of drugs with longer half-lives may be prolonged or incomplete.

Cautious rechallenge may be considered only after all signs and symptoms of drug-induced hepatocholestatic injury have resolved and only when other nonhepatotoxic alternative therapies are unavailable. The rechallenge dose may be reduced by at least one-half and titrated upward to a desired dose over several months, if tolerated.[1-14,16,17,20,21,56,93,94,99] Serum aminotransferase concentrations should be monitored frequently (i.e., at least weekly) during rechallenge.

A culprit medication should be permanently discontinued if fulminant hepatocholestatic injury or immune-mediated hepatic injury has occurred. To prevent further injury, medications with dose-dependent toxicity should be removed rapidly from the patient's system by aspiration, activated charcoal, or dialysis. Determination of serum concentration of the offending medication can help gauge the success of removal strategies. These concentrations should be obtained daily, but more frequent monitoring may be necessary in cases of severe hepatotoxicity or as required by institutional protocol.

In most cases, management of patients with drug-induced liver disease is limited to supportive care. **Table 38-10** describes management of drug-induced hepatocholestatic diseases and associated complications.[94,99-186,192,193] There are very few rescue treatments for drug-induced liver disease, and some potential rescue treatments are not available for human use in the United States. Mevalonic acid, for example, could help prevent and/or ameliorate cholestatic injury due to hydroxymethylglutaryl coenzyme A reductase inhibitors (statins).[100] Other rescue options are time-sensitive. Folic acid, for example, is protective against methotrexate-induced hepatotoxicity when given within 24 hours of exposure.[193]

A rescue treatment proven effective for acetaminophen-induced hepatitis is *N*-acetylcysteine (NAC). Although NAC is typically administered within 24 hours of acetaminophen ingestion, a randomized, placebo-controlled study showed that NAC infusions of 6.25 mg/kg/hr reduced mortality, the incidence of cerebral edema, and vasopressor requirements in patients with acetaminophen-induced fulminant liver failure who presented >24 hours after ingestion.[101] All patients had undetectable serum acetaminophen concentrations when NAC was initiated, suggesting that NAC may have therapeutic effects other than its glutathione-replenishing ability (via providing the precursor L-cysteine). Pennyroyal oil and carbon tetrachloride can deplete glutathione, and some evidence suggests that administering NAC shortly after exposure to these agents is beneficial.[102-106] Case reports also indicate that NAC may be beneficial in the treatment of acute hepatic failure caused by valproic acid and sulfasalazine.[107,108]

In theory, NAC may be beneficial for other drug-induced causes of direct hepatotoxicity because it facilitates the replenishment of glutathione, acts as an antioxidant, decreases inflammation by reducing leukocyte chemotaxis and suppressing the expression of nuclear factor-κB, and enhances the synthesis of nitric oxide to increase oxygen delivery.[109,110] Studies have demonstrated benefits of treatment in certain cases of nonacetaminophen drug-induced hepatic injury.[111-113] However, until more evidence is available, intravenous NAC should generally be reserved for use in the situations described previously.

Corticosteroids reduce the inflammatory response to toxic stimuli. Prednisone 10–80 mg daily may reduce the inflammatory reaction associated with immune-mediated hypersensitivity reactions. Azathioprine 50–150 mg daily may be substituted or added.[115,116] Because corticosteroids are possibly effective for alcohol-induced hepatitis, several studies have investigated their clinical use for other causes of hepatitis.[117-120] Unfortunately, no trial has specifically studied the effectiveness of corticosteroids in patients with drug-induced hepatitis. The results of a multicenter study that enrolled 62 patients with acute hepatic failure found that 9 of 10 patients with drug-induced liver failure (6 due to halothane, 2 due to methyldopa, 1 due to isoniazid, and 1 due to propylthiouracil) died despite daily therapy with hydrocortisone 40–800 mg.[121] Until additional studies are conducted, corticosteroids cannot be routinely recommended for the treatment of drug-induced hepatitis. Corticosteroids may have a role in certain case-specific scenarios, including use in patients with lesions resembling immune-mediated hypersensitivity reactions or macrovesicular steatosis caused by agents other than alcohol, including methotrexate, parenteral lipids, and warfarin.[122] Another potential role for corticosteroids is in patients demonstrating hypersensitivity with extrahepatic manifestations (Table 38-7).

Table 38-10 Management of Drug-Induced Hepatic and Cholestatic Diseases and Associated Complications[94,99-186,192,193]

Agent or Symptom	Management
Acetaminophen toxicity (unintentional or chronic), carbon tetrachloride, pennyroyal oil, other cytotoxic agents (case-specific)100-112	NAC intravenously 150 mg/kg (MAX: 15,000 mg) over 1 hr, then 50 mg/kg (MAX: 5,000 mg) over 4 hr, then 6.25 mg/kg/hr (MAX: 10,000 mg) for 16 hr, may continue until resolution if clinically indicated or NAC enterally 140 mg/kg loading dose, then 70 mg/kg every 4 hr for 17 additional doses
Alcoholic hepatitis99,114	Prednisolone 40 mg enterally daily for 4–6 weeks or pentoxifylline 400 mg enterally 3 times daily for 4 weeks
Ascites145-150,156-162	Fluid restriction 1–2 L/day and sodium restriction 1–2 g/day and furosemide 40 mg intravenously or enterally daily and spironolactone 100 mg enterally daily (diuretics titrated to remove 0.5–2 kg/day) ± large-volume paracentesis if diuretic- refractory, abdominal pain, or breathing difficulties
Cerebral edema with increased intracranial pressure145-150,176-182	Minimize agitation, hyperthermia, pain, hypoxia, and acidosis ± mannitol 25–50 g intravenously as needed for intracranial pressure >20 mm Hg and serum osmolarity <320 mOsm/kg (or hypertonic saline to keep serum sodium 145–155 mEq/L) ± hyperventilation for pCO_2 near 35 mm Hg ± pentobarbital or thiopental 250 mg intravenously as needed for intracranial pressure >20 mm Hg ± hypothermia 32–35°C
Cholestasis128-132	Ursodiol 300–600 mg daily enterally daily until resolution
Coagulopathy (INR >1.5)141-154	Vitamin K 10 mg intravenously or enterally daily ± fresh-frozen plasma ± platelets (to keep platelet count >50×109/L) ± desmopressin acetate 0.4 mcg/kg intravenously ± factor VIIa 10–100 mcg/kg intravenously (usually reserved for refractory hemorrhage)
Electrolytes133	Correct hypokalemia, hypomagnesemia, and hypophosphatemia
Encephalopathy167-175	Lactulose enterally or rectally 30 mL as needed to produce 2 stools daily ± enteral antibiotic (rifaximin 200–400 mg 3 times daily or metronidazole 500

	mg 2–4 times daily)
Hepatorenal syndrome[133,187-192]	Renal replacement therapy ± vasopressin 0.1–0.4 units/min (or midodrine 2.5–10 mg enterally 3 times daily + octreotide)
Hyperglycemia[145-150]	Short-acting (regular) insulin intravenously or subcutaneously
Hypoglycemia[145-150]	Dextrose 50% (*w/v*) intravenously
Immune-mediated hypersensitivity reaction (case-specific)[115-123]	Prednisone 10–80 mg enterally daily for 4–6 weeks ± azathioprine 50–150 mg enterally daily
Pruritus[140]	Cholestyramine 4 g enterally twice daily or colestipol 5 g enterally twice daily (titrate to relief or diarrhea) ± rifampin 600 mg enterally daily ± phenobarbital 60–120 mg enterally daily ± chlorpromazine 150–300 mg orally daily ± naloxone 20 mg subcutaneously daily ± ondansetron 8 mg intravenously or enterally once
Spontaneous bacterial peritonitis[156-166]	Antibiotic (third-generation cephalosporin, fluoroquinolone, or extended-spectrum penicillin) for 5–7 days, and albumin 1.5 g/kg intravenously at diagnosis then 1 g/kg intravenously 3 days later
Valproic acid toxicity[124-127]	L-carnitine 50–300 mg/kg intravenously daily until resolution
Variceal hemorrhage[161-163,183-185,186]	Hemodynamic resuscitation and endoscopy (banding preferred) and octreotide 50 mcg intravenously, then 25–50 mcg/hr for 72 hr ± transjugular intrahepatic portosystemic shunt
Veno-occlusive or veno-thrombotic disease[134-139]	Stent placement or angioplasty ± thrombolysis (rTPA 2 mg then 0.5–1 mg/hr infused locally for 24 hr) ± anticoagulation ± transjugular intrahepatic portosystemic shunt

NAC = *N*-acetylcysteine, INR = international normalized ratio, pCO_2 = partial pressure of arterial carbon dioxide, rTPA = recombinant tissue plasminogen activator.

Several other agents have reported potential in treating multiple etiologies of hepatitis, including colchicine, gemfibrozil, betaine glucuronate, ursodiol, pentoxifylline, α-tocopherol, nitric oxide, methionine, vitamin E, L-carnitine, and silymarin (milk thistle).[123,124] Only L-carnitine and silymarin have been studied for reversal of drug-induced liver dysfunction.

L-carnitine induces ureagenesis, facilitates fatty acyl transport, and reduces inflammation by inhibiting TNF. The results of a retrospective study of 92 patients with apparent fulminant liver failure secondary to valproic acid showed that L-carnitine therapy at unspecified doses improved survival from 10% to 48%.[125,126] It should be noted, however, that specific data describing the patients, severity of liver injury, and morphologic and histologic pathologies were not presented. The typical dose of intravenous L-carnitine is 50–100 mg/kg/day given in divided doses every 6–8 hours, and therapy should be initiated as soon as possible after suspected/confirmed exposure.

Silymarin, also known as milk thistle, is an herbal supplement used sometimes by patients to “protect the liver” when taking agents with hepatotoxic potential. Silymarin is reported to possess antioxidant, anti-inflammatory, and antifibrotic properties that protect hepatocytes from lipid peroxidation. Unfortunately, beneficial effects have not been substantiated. A meta-analysis of 14 trials of silymarin used in patients with chronic liver disease (two studies of drug-induced liver diseases) found that ALT was reduced by only 9 international units per liter ($p = 0.05$).[127] AST, albumin, and prothrombin time were not significantly affected. Although silymarin was thought to have potential to inhibit hepatitis C virus (HCV) replication, a randomized, controlled trial evaluating high-dose oral silymarin administration was unable to show improvement in concentrations of ALT or HCV RNA in patients with HCV unsuccessfully treated with interferon therapy.[194] As a result, silymarin cannot be recommended in the treatment or prevention of drug-induced hepatotoxicity or other types of hepatic disease.

Patients with drug-induced cholestasis may require long-term daily treatment with ursodiol 300–600 mg/day to dissolve cholesterol gallstones and inhibit apoptosis.[21,56,128-132] Anticoagulation therapy, thrombolytic therapy, or both should be considered after stent placement or angioplasty for drug-induced veno-occlusive or venothrombotic diseases.[134-139] If there is evidence of hepatic impairment or ascites, patients with veno-occlusive or venothrombotic disorders should receive minimal sodium (<2 g/day) and may require diuretics for the removal of accumulated fluid, similar to the treatment of ascites with other etiologies.[134-139]

Ultimately, patients with fulminant liver failure who do not respond to the measures described above will likely require liver transplantation to survive. Unfortunately, only 50% of patients with drug-induced liver failure receive a liver transplant, primarily due to the limited availability of organs and patients' relatively short survival time.[62,195] The use of liver-assist devices or hepatic regeneration therapy with agents such as malotilate is not common, and most data supporting their use are from case reports.[187,191] Extracorporeal liver-assist devices may be artificial or cell-based.[189] Artificial devices use either conventional dialysis along with hemodialysis with a 5–10% albumin dialysate solution over an albumin-impermeable membrane or a fractionated plasma separation technique that uses a membrane with a 250-kDa cutoff between circuits, thereby making the membrane permeable to albumin.[189] Cell-based devices incorporate hepatocytes from various sources and have the theoretical advantage of not only providing blood purification through dialysis but also providing hepatocyte-specific functions (e.g., protein synthesis, ureagenesis, gluconeogenesis, and detoxification through CYP activity).[189] A meta-analysis suggests that liver-assist devices may reduce the incidence of encephalopathy by 33% but do not alter mortality.[187] These devices may, however, improve the likelihood that a patient will survive until transplantation is possible.[188] Devices are not currently available clinically, but represent avenues of future research. In patients with portal hypertension and refractory bleeding or refractory ascites, transjugular intrahepatic portosystemic shunt may be considered to provide time until a liver transplantation can be performed. This approach, however, is associated with worsening encephalopathy.[186]

Liver dysfunction may be associated with pruritus, coagulopathy, malabsorption of fat-soluble vitamins (vitamins A, D, E, K), glycemic dysregulation, ascites, spontaneous bacterial peritonitis (SBP) or other infectious processes, encephalopathy with increased intracranial pressure (ICP), variceal hemorrhage, hepatorenal syndrome, electrolyte abnormalities, metabolic acidosis, and cardiovascular collapse. Biliary dysfunction may cause osteoporosis and hypercholesterolemia. The majority of these are chronic manifestations seen in patients with cirrhosis.

Pruritus in patients with liver dysfunction is likely due to the accumulation of bile acids, even though the concentration of bile acids in the skin does not correlate with the degree of pruritus.[140] Management of this condition is difficult because traditional histamine$_1$-receptor antagonists (e.g., promethazine) typically offer little relief from itching. First-line treatment is the administration of a bile acid sequestrant (e.g., cholestyramine or colestipol).[140] Doses are initially low (cholestyramine 4 g or colestipol 5 g daily or twice daily) and increased over a period of several weeks until symptomatic relief is achieved or constipation develops. Both of these agents may bind and reduce the gastrointestinal absorption of other drugs. Consequently, dosing schedules should be adjusted so that other drugs are given at least 1 hour before or 4 hours after the sequestrant. In cases in which the bile-acid sequestrant is ineffective or not tolerated, therapy with rifampin in a dose of 600 mg daily may be tried.[140] Symptomatic relief usually occurs within 1–3 weeks of initiating rifampin, likely due to enzyme induction and enhanced clearance of bile acids. Caution is necessary when rifampin is used in this patient population. Serum concentrations of liver enzymes and bilirubin should be obtained within 2 weeks of initiating therapy to ensure that the drug is not worsening hepatic disease. Phenobarbital may alleviate pruritus and also provides sedation. Chlorpromazine 25–100 mg every 6 hours produces variable results. As with rifampin, serum concentrations of liver enzymes and bilirubin should be determined within 2 weeks of initiating therapy with chlorpromazine. Daily subcutaneous administration of naloxone has been shown to be effective.[140] A single intravenous dose of ondansetron 8 mg has been shown to alleviate pruritus within 24 hours of administration in one case series, presumably by blocking serotonin (5-hydroxytryptamine type 3) receptors on sensory nerve endings.[140]

Hepatic dysfunction alters coagulation and fibrinolysis through several mechanisms, including reducing concentrations of coagulation factors V, VII, IX, X, XI, prothrombin, thrombin-activated fibrinolysis inhibitor, endogenous anticoagulants (proteins C, S, Z; heparin cofactor II; Z-dependent protease inhibitor; antithrombin), producing defective vitamin K-dependent coagulation factors (VII, IX, X, prothrombin) and increasing concentrations of tissue plasminogen activator, plasminogen activator inhibitor, and von Willebrand factor.[141,142] Renal dysfunction frequently accompanies hepatic dysfunction and usually increases bleeding risk due to acquired platelet dysfunction and abnormal platelet–vessel wall interaction.[141,142] Hepatic injury prevents efficient use of vitamin K, and a dose of 10 mg of vitamin K can reverse coagulopathy to some extent in many patients with mild-to-moderate liver dysfunction.[143-150] The treatment of coagulopathy secondary to drug-induced hepatic dysfunction frequently necessitates the administration of exogenous clotting factors (e.g., fresh-frozen plasma or cryoprecipitate).[145-150] Exogenous platelets should be administered only when life-threatening thrombocytopenia is present.[151] Intravenous desmopressin acetate at maximum doses of 0.4 mcg/kg promotes the release of factor VIII from platelets and reverses coagulopathy with variable success.[151] Intravenous recombinant factor VIIa in a dose of 10–100 mcg/kg rapidly reverses coagulopathy and may alleviate hemorrhagic episodes; but these effects last less than 6 hours so this treatment is usually reserved for cases of refractory hemorrhage.[152,153] Higher doses of recombinant factor VIIa may be associated with thrombosis.[154] In general, the INR should be maintained at a value <1.5 and the platelet count ≥50,000 per cubic millimeter. However, reversing coagulopathy may require substantial fluid administration that can induce ascites and intracranial hypertension, negating the ability to use coagulopathy as a prognostic marker.[145-150] Although the production of endogenous thrombopoietin is frequently diminished in patients with severe liver dysfunction, there is no evidence supporting the routine use of exogenous thrombopoietin.[151]

Fat-soluble vitamins (A, D, E, K) should be administered with careful attention to the dose of vitamin A because it may induce liver failure at high doses or worsen existing injury at therapeutic doses. In these situations, vitamin A induces hepatic inflammation and diminishes the antioxidant capacity of the liver.[155]

Hypoglycemia is a common manifestation of liver dysfunction because the production of glucagon is impaired and hepatic glycogen stores are minimal.[145-150] Patients with fulminant liver dysfunction are often hypervolemic; therefore, the intravenous administration of high concentrations of dextrose (50% *w/v*) may be needed to correct hypoglycemia without adding volume. Patients may develop hyperglycemia due to peripheral insulin resistance and the inability of the liver to convert glucose to glycogen.[145-150] Subcutaneous or intravenous insulin can be used to control hyperglycemia.

Portal hypertension and arterial vasodilation produce ascites by activating the renin–angiotensin–aldosterone–vasopressin system to increase intravascular blood volume. Peritoneal fluid collects when an elevated hepatosplanchnic pressure forces the passage of fluid from the sinusoidal lumen into the interstitial spaces because the endothelial cells that line the sinusoids are compromised.[156-162]

Therefore, ascites should be treated with fluid restriction (1–2 L/day), sodium restriction (1–2 g/day), and the administration of diuretics, preferably furosemide and spironolactone in doses of 40 mg/day and 100 mg/day, respectively.[145,150,156-162] These doses may be titrated over time to 160 mg/day and 400 mg/day, respectively. The goal of diuretic therapy is to remove fluid at a rate of 0.5 kg/day in patients without peripheral edema and 2 kg/day in patients with peripheral edema. Large-volume paracentesis (>5 L) may be performed if the patient has severe abdominal pain or breathing difficulty.[156-162] Albumin (8 g for each liter of ascitic fluid removed) administered during or immediately after paracentesis can help prevent circulatory and renal dysfunction.[145-150,157-162]

Small-volume paracentesis (<2 L) is used to evaluate patients with new-onset ascites for the presence of SBP, and an ascitic fluid polymorphonuclear count of ≥250 cells per cubic millimeter is considered diagnostic.[156-165] SBP occurs when bacteria translocate from the intestinal tract to the peritoneum via the mesenteric lymphatic system. This complication of hepatic disease is secondary to impaired gastrointestinal motility, damage to the intestinal mucosa, gastrointestinal bacterial overgrowth, low concentrations of protein and complement in the ascitic fluid, impaired activity of the reticuloendothelial system including Kupffer cells, and reduced neutrophil function.[164,165] Antibiotic therapy for 5–7 days is indicated for the treatment of patients with SBP.[156-165] Therapy should be designed to cover the most likely organisms and penetrate the ascitic fluid. Coverage for *Escherichia coli*, *Streptococcus pneumoniae*, *Klebsiella* species, and other enteric gram-negative organisms should be provided. Third-generation cephalosporins (cefotaxime, ceftriaxone), extended-spectrum penicillins (ampicillin–sulbactam), and fluoroquinolones (ciprofloxacin) are all effective in eradicating these organisms, with resolution rates generally ≥90%.[165] Empiric selection of initial antibiotic therapy should consider the local antimicrobial resistance patterns. Albumin in a dose of 1.5 g/kg given at the time of diagnosis and 1 g/kg given 3 days later has been shown to reduce the incidence of renal impairment and hospital mortality in patients with SBP.[166] Prophylactic antibiotics for the prevention of SBP in patients with ascites may be warranted when fulminant liver failure is present.[160-165]

Encephalopathy is a metabolic disorder of mental activity, neuromuscular function, and consciousness associated with hepatic disease. It is believed to be caused by the accumulation of substances (e.g., ammonia) that are efficiently metabolized/eliminated under normal conditions but accumulate with liver dysfunction.[167-169] Single measurements of serum ammonia concentrations do not reflect the degree of encephalopathy, but trends in serial measurements correlate with the progression or reversal of encephalopathy.[167-169] Initial treatment of encephalopathy should include the reversal of precipitating factors (including hemorrhage, excess dietary protein, azotemia, infection, constipation, and metabolic/electrolyte disturbances) and the discontinuation of central nervous system depressants.[167-169] Pharmacotherapy of encephalopathy may be initiated with enteral or rectal lactulose (30 mL as often as hourly until stool is produced and then 3–4 times daily as needed to produce two to three soft stools per day) and enteral rifaximin (200–400 mg 3 times daily) or metronidazole (500 mg 2–4 times daily).[145-150,167-170] Meta-analysis has shown that lactulose improves encephalopathy.[171] Neomycin (1–2 g 4 times daily) is used for encephalopathy in rare cases, and caution is warranted as it is associated with nephrotoxicity.[170] Protein restriction is not recommended unless other treatment modalities fail to control symptoms, and nutritional products containing branched-chain amino acids may reduce the degree of encephalopathy, although major outcomes, such as returning to baseline mental status, length of hospital stay, and survival do not improve.[172-174]

Altered mental status should be investigated using computed tomography to rule out intracranial hemorrhage. Insertion of an ICP monitoring device may be considered but may constitute an unacceptable risk for the patient when coagulopathy is present.[176,177] The use of an ICP monitor is associated with hemorrhage and 30-day survival after liver transplantation has been found to be similar in both monitored and nonmonitored patients.[178] Treatment of increased ICP should include minimizing agitation with short-acting benzodiazepine agents, providing analgesia with short-acting opioid agents, controlling hyperthermia, and minimizing acidosis and hypoxia.[145-150,176,177] Cerebral edema and increased ICP may be treated with intravenous mannitol 25–50 g as needed to keep the ICP <20 mm Hg and the serum osmolality between 310–320 mOsm/kg.[167-169,176,177] Mannitol may accumulate in astrocytes if renal failure is present and may cause rebound cerebral edema. Hypertonic saline (3% *w/v*) administered to a target serum sodium concentration of 145–155 mEq/L may be used as an alternative to mannitol but can contribute to serum sodium irregularities.[179]

Hyperventilation to maintain the partial pressure of arterial carbon dioxide near 35 mm Hg should reduce ICP without substantially compromising cerebral blood flow, but this effect is limited to several hours.[145-150,180] Intravenous thiopental or pentobarbital may be used if mannitol is unsuccessful or contraindicated.[145-150,176,177] Mild hypothermia (32–35°C) is also used in the treatment of elevated ICP. This therapy maintains hepatic function by decreasing ischemia-reperfusion injury and the inflammatory response; however; it is associated with coagulopathy, electrolyte abnormalities, altered hemodynamics, variable glucose control, and rebound intracranial hypertension during rewarming.[181,182]

Variceal hemorrhage and hepatorenal syndrome are rarely associated with idiosyncratic drug reactions. Varices are caused by portal hypertension and develop when the portal pressure gradient exceeds 10 mm Hg, resulting in the development of portosystemic collateral circulation.[161-163,183,184] A variceal hemorrhage should be treated with endoscopic procedures (banding is preferred) followed by the administration of octreotide (50 mcg bolus followed by intravenous infusion of 25 or 50 mcg/hr for 3–5 days).[161-163,183,184] Octreotide reduces the rate of rebleeding and transfusion requirements.[185] In some countries, terlipressin (a vasopressin analogue) is available and has demonstrated improved survival.[183] Acute renal failure may require renal dialysis, but hepatorenal syndrome may be temporarily alleviated by intravenous vasopressin infusion (0.1–0.4 units/minute) or the combination of octreotide and midodrine (2.5–10 mg 3 times daily).[192]

Common electrolyte abnormalities associated with liver dysfunction include hypophosphatemia, hypokalemia, and hypomagnesemia. Electrolyte replacement may be required. Hypervolemic hyponatremia is common and usually asymptomatic even when sodium concentrations are profoundly low; however, it may indicate the onset of hepatorenal syndrome or increase the predictive mortality potential for Model for End-stage Liver Disease scoring in cirrhosis.[133] The benefits of raising serum sodium concentrations in severe hyponatremia are controversial in patients with severe hepatic dysfunction (e.g., cirrhosis). Diuretic therapy combined with fluid restriction can improve serum sodium concentrations.[133] Intravenous sodium chloride should be administered only when patients are symptomatic (e.g., when seizures are present), as increases in serum sodium concentrations are transient and the excess fluid may precipitate ascites.

Vasopressin receptor antagonists (e.g., conivaptan and tolvaptan) are a novel class of diuretics used to correct hyponatremia. Unlike loop diuretics, vasopressin receptor antagonists increase urine flow and decrease urine osmolality while increasing plasma osmolality without increasing the renal elimination of sodium. All vasopressin receptor antagonists are contraindicated in severe hepatic impairment, and tolvaptan should generally be avoided with any underlying liver disease.[196,197] Following liver transplantation, the restoration of hepatic function and isotonic fluids received during surgery will induce rapid correction of hyponatremia. However, if baseline sodium concentrations are too low, this correction may be rapid enough to induce osmotic demyelination syndrome. Osmotic demyelination syndrome can occur with rapid rises in sodium concentrations (>9 mEq/L in 24 hours and ≥18 mEq/L in 48 hours), which can be associated with cerebral edema and severe neurologic complications.[198,199] Therefore, in patients with a serum sodium concentration <130 mEq/L awaiting liver transplant, administration of hypertonic saline for slow correction of hyponatremia prior to transplantation may help prevent this potential complication.[198]

Systemic complications (e.g., metabolic acidosis and cardiovascular collapse) may cause acute hypoperfusion of the liver, commonly called shock liver or ischemic hepatitis. Treating the underlying cause of shock liver generally leads to resolution of hepatic injury. If long-term complications of biliary dysfunction occur (e.g., osteoporosis or hypercholesterolemia), treatment should be implemented according to current practice guidelines, with special consideration for dose adjustments for hepatic impairment.

INFORMATION FOR PATIENTS

Patients taking agents that may cause hepatocholestatic injury should be instructed to consult their healthcare provider if they experience nausea, vomiting, unexplained weight loss, decreased appetite, or abdominal pain that lasts several days and cannot be attributed to other causes. Patients with altered mental status, increased abdominal girth, peripheral edema, bleeding episodes, protracted pruritus, jaundice, or reduced urine production should receive immediate medical attention. In some cases, no symptoms may be present and medical tests (imaging, biopsy, and/or bloodwork) may be required. Patients should be instructed not to take any nonprescription medications or herbal products without first consulting their healthcare provider. Patients should inform their healthcare provider of all medications (including herbal remedies and dietary supplements) they are taking to avoid drug–drug interactions. All patients should be educated about their medications and risk factors, including alcohol, illicit drugs, and other environmental exposures. It is important to emphasize to patients that they should only take their medications in doses recommended or prescribed by their healthcare provider. This may help avoid toxicity, but some medications can cause toxicity even at recommended doses (idiosyncratic reactions). Toxicity may occur within days or months of starting a medication. The most effective treatment for drug-induced liver toxicity is stopping or avoiding the offending medication. In most cases, the liver repairs itself but may take several months to heal. In severe cases (e.g., liver failure or cirrhosis), liver transplantation may be needed.

CHAPTER 39

Pancreatitis

Pramodini B. Kale-Pradhan and Sheila M. Wilhelm

Pancreatitis, an inflammatory process of the pancreas, may be described as either acute, in which the normal function of the pancreas returns, or chronic, in which the damage to pancreatic function is irreversible.[1] Although a number of drugs have been reported to cause pancreatitis, the cause-and-effect relationship is often difficult to verify. It is unclear how drugs cause pancreatitis, although several mechanisms have been hypothesized, including immune-mediated, direct pancreatic toxicity, pancreatic duct constriction, thrombosis, and metabolic effects.

CAUSATIVE AGENTS

Table 39-1 lists the agents implicated in drug-induced pancreatitis. Typically, drugs are associated with acute pancreatitis although there are some reports of drug-induced chronic pancreatitis as well. One review reported that 44 of the top 100 most frequently prescribed medications in the United States have been associated with acute pancreatitis.[2] Drug-induced pancreatitis has no features that allow it to be differentiated from other forms of the disorder.[3] Mallory and Kern classified drugs that may cause pancreatitis into three groups: those with a definite association, those with a probable association, and those with a questionable association.[4] Drugs are classified as having a definite association if the disease develops during treatment with the drug, disappears after the drug is withdrawn, and returns when the patient is rechallenged. Drugs are classified as having a probable association with pancreatitis if an association is thought to be likely and one or two of the definite association criteria are met. Drugs are classified as having a questionable association if the supporting evidence is inadequate or contradictory. In addition to the Mallory and Kern system, two additional classification systems have been proposed and are also frequently cited in the literature. Trivedi and Pitchumoni proposed a system that modified the three-group classification system giving more weight to the number of cases reported and positive rechallenge.[2] Badalov's system categorizes drug-induced pancreatitis using five classes.[5] Class Ia includes drugs with at least one case report, evidence of a positive rechallenge, and exclusion of other causes of acute pancreatitis. Class Ib is similar to class Ia, but in this class, other causes of acute pancreatitis could not be ruled out. Criteria for Class II drugs include at least four case reports with a consistent latency period for at least 75% of the cases. Class III drugs have at least two case reports but do not have rechallenge data or a consistent latency period. Finally, Class IV drugs have one case report without rechallenge data.

Table 39-1 Agents Implicated in Drug-Induced Pancreatitis[1-7,11,23,38,43,67,68,170,544]

Drug	Incidence	Level Evide
DEFINITE ASSOCIATION		
5-ASA[112,198,199,201,202,204-217,496]	NK	B
ACE inhibitors (benazepril, enalapril, lisinopril, captopril, quinapril, ramipril)[16,44-54,57,58,61-65,67,510,511,538,545,546]	0.3–1.07%	B
Amiodarone[483-486]	0.01–0.02%	B
Asparaginase[131-135,138-140,142-147,149-152,155-159,161-163,165-169,503]	2–18%	B
Azathioprine[10,12,16,103-107,109-111,113,116,117,120-123]	4.5–5.3%	B

Itraconazole[584]	NK	C
Lamivudine[562,585]	<0.5%	C
Minocycline[257,258,261]	NK	B
Olanzapine[586-589]	NK	C
Omeprazole[74,75]	NK	C
Orlistat[443,590-592]	NK	C
Piroxicam[178,513]	NK	C
Procainamide[593]	NK	C
Ribavirin[37,424,426,429]	NK	C
Stavudine[562,594,595]	NK	C
Vinblastine[231]	NK	C
Vincristine[231]	NK	C
Zalcitabine[562,596]	<1%	C

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials;

—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective stu case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one more published case reports or case series.

EPIDEMIOLOGY

Drugs are found responsible for pancreatitis in approximately 0.1–5.3% of patients who are diagnosed with the disease.[6-12] Drugs are the cause in 13–30% of pancreatitis cases in children.[13-15] Pediatric patients with drug-induced pancreatitis have longer hospital stays and are more likely to require parenteral nutrition than those where the etiology is not drug-related.[15] The incidence of acute drug-induced pancreatitis is higher in patients with disease states that predispose to the development of pancreatitis, including infection with the human immunodeficiency virus (HIV), acquired immune deficiency syndrome (AIDS), renal transplantation (immunocompromised patients), and inflammatory bowel disease (autoimmune diseases).[9,11] Other subgroups with higher incidences include the very young or very old and females.[10-12]

A case-control study was conducted at a network of 51 hospitals in Berlin from 2002 to 2011.[16] During this time, 64 of 102 cases of acute pancreatitis were determined to be possibly related to drugs, including fenofibrate, formoterol and budesonide, ramipril and hydrochlorothiazide, lisinopril, and azathioprine.

There is a much higher incidence of drug-induced pancreatitis in patients who are HIV positive and treated with didanosine.[17-22] In contrast, the incidence of didanosine-induced pancreatitis is substantially lower in patients without HIV.[23-25] Pancreatitis develops 10–20 weeks after initiation of didanosine with an incidence of up to 9%.[20,21,23,25-41]

Angiotensin-converting enzyme (ACE) inhibitors were implicated as the cause of pancreatitis in 209 of 2,749 reports of drug-induced pancreatitis that the World Health Organization (WHO) received from 1968 to 1993.[42] More recently, over 300 cases of drug-induced pancreatitis were associated with enalapril or captopril.[43] The estimated incidence of ACE inhibitor-associated pancreatitis ranges from 0.3% to 1.07%.[44] A retrospective cohort study of 174,824 elderly patients prescribed ACE inhibitors reported an incidence of nine per 10,000 person-years, which was not significantly different from control groups.[45] Several cases of ACE inhibitor and angiotensin II receptor antagonist-induced pancreatitis have been reported.[46-62] Pancreatitis may develop several months after initiation of ACE inhibitor therapy and may recur with rechallenge with a latency period ranging from 4 to 26 months.[63-65] Acute necrotizing pancreatitis developed in a patient receiving sulindac and hydrochlorothiazide for more than 6 years and lisinopril for 1 year and progressed to chronic pancreatitis possibly due to repeated subclinical drug-induced acute pancreatitis and a third insult involving lisinopril.[66] ACE inhibitors are associated with an increased risk of acute pancreatitis, particularly in the first 6 months of therapy, and the risk increases as the daily dose increases.[67]

From 1968 to 1993, the WHO received 127 case reports of pancreatitis associated with histamine H_2 receptor antagonists.[68] The association between cimetidine and pancreatitis is probable, and there are numerous published reports.[69-74] There is a small number of case reports of pancreatitis associated with the use of proton pump inhibitors. At least one case report of omeprazole-induced pancreatitis has been published.[75,76] However, a retrospective case-control study of more than 180,000 subjects did not find an increased risk.[74]

There are at least eight well-documented cases of metronidazole-induced pancreatitis.[77-84] In these cases, the onset of symptoms ranged from 12 hours to 7 days after initiation of therapy and resolved after discontinuation of the drug.

Several patients experienced recurrence with rechallenge of metronidazole.[77-79,83-85] In addition, a population-based case-control study reported a threefold increased risk of acute pancreatitis in patients treated with metronidazole.[86]

There are numerous reports of 3-hydroxy-3-methyl-glutaryl-CoA (Hmg-CoA) reductase inhibitor- or statin-induced pancreatitis in the literature.[87-98] Meta-analyses demonstrate conflicting results.[88,99] The risk for pancreatitis does not appear to be dose-related.[100] In several case reports, patients receiving statins experienced other adverse effects including myalgia or rhabdomyolysis before the onset of acute pancreatitis.[101] Drug interactions mediated through CYP3A4 have been hypothesized to contribute to the development of statin-induced pancreatitis; therefore, statins not metabolized by CYP3A4, such as pravastatin, may present a lower risk for drug-induced acute pancreatitis than other statins. Pancreatitis can occur at any time but may be more likely after many months of treatment with statins.[101]

Azathioprine and 6-mercaptopurine are potent immunosuppressive agents associated with pancreatitis with an incidence of 3.3–5.3%.[102-120] Several epidemiological studies have identified azathioprine as one of the most frequent causes of drug-induced acute pancreatitis.[10,12,16] The median time to onset of pancreatitis after initiation of therapy was 21 days with females at higher risk.[120-123] Case series have documented successful treatment with 6-mercaptopurine after azathioprine had been discontinued as a result of acute pancreatitis.[124,125] A meta-analysis determined that approximately one-third of patients are able to tolerate mercaptopurine following an episode of azathioprine-induced pancreatitis.[126] A small, prospective, open-label study of patients resistant and intolerant to azathioprine and mercaptopurine concluded that thioguanine may be an alternative treatment as patients who had experienced an episode of pancreatitis with azathioprine or 6-mercaptopurine did not develop pancreatitis while receiving thioguanine.[127] Genomic studies have attempted to identify genetic variants useful in predicting patients at risk for thiopurine-induced pancreatitis. One genome-wide study reported an association within the class II HLA region with almost twice the risk for homozygotes compared to heterozygotes.[128] No association was found between pancreatitis and thiopurine methyltransferase polymorphisms.[128,129] A variant allele that codes for the enzyme xanthine dehydrogenase was potentially associated with an increased risk of pancreatitis compared to the standard genotype.[130]

L-asparaginase induces pancreatitis in 2–18% of patients.[131-134] There are numerous case reports of L-asparaginase-induced pancreatitis with and without fatalities.[135-151] Two other preparations have largely replaced L-asparaginase: erwinia carotovora-derived L-asparaginase (erwinia L-asparaginase) and polyethylene glycol-L-asparaginase (PEG-asparaginase, Oncaspar). The available literature is inconsistent and has not established a clear difference in incidence of pancreatitis among the three preparations. Some early studies suggested that erwinia L-asparaginase was associated with a lower incidence of pancreatitis when compared to L-asparaginase, although other studies found no difference.[151-157] The incidence of pancreatitis associated with PEG-asparaginase is similar to that of L-asparaginase, but a few studies suggested that the rate of pancreatitis may be higher with PEG-asparaginase.[156,158-165] The variation in rates across studies may be due to differences in criteria used to define and classify acute pancreatitis, variation in number of doses, or differences in chemotherapy regimens.[134,151,156] However, these factors have not been found to be predictive of the risk of asparaginase-induced pancreatitis.[134,151,156,163,165-167] Pancreatitis induced by preparations of asparaginase usually occurs during administration of the drug, often after just one or a few doses.[133,138,149,166-169] Pancreatitis may occur during any phase of chemotherapy, and cases of pancreatitis have been reported as long as 16 weeks after therapy has been discontinued.[4,131,134,156,166] Fatalities have been rarely reported as a result of asparaginase-associated pancreatitis in recent studies, which may reflect improved supportive care measures.[134,167] Rates of recurrence with rechallenge have ranged from 0% to 63%.[134,156,157,167]

Pancreatitis secondary to hypercalcemia occurs in up to 7% of patients.[170,171] Pancreatitis has been associated with intravenous calcium administration, total parenteral nutrition, and over-the-counter antacids containing calcium carbonate.[172-176] Hypercalcemia-related pancreatitis is more common in patients who have undergone renal transplantation, with an approximate incidence of 11%.[177]

The incidence of pancreatitis induced by nonsteroidal anti-inflammatory drugs (NSAIDs) appears low. In a population-based study of over 100,000 users of piroxicam, naproxen, or diclofenac, only one case of pancreatitis occurred (in a patient receiving piroxicam).[178] In contrast, there are numerous reports of sulindac-induced pancreatitis, including reports of recurrence after rechallenge.[179-186] Reports suggest pancreatitis develops within 2 weeks to 9 months following initiation of sulindac therapy; however, a latency period of up to 5 years also has been reported.[66,186,187]

Rare, acute pancreatitis has been reported with acetaminophen overdose.[188-196] In a retrospective review of 814 acetaminophen overdoses, hyperamylasemia was frequent, but acute pancreatitis rarely occurred.[197] A poor prognosis was associated with higher serum amylase concentrations.

Salicylate-induced pancreatitis has been reported, particularly in association with poisoning or aspirin desensitization.[198-200] Pancreatitis has been reported in association with the salicylate derivatives sulfapyridine and sulfasalazine.[201-215] In a retrospective analysis of serious adverse events, pancreatitis was reported seven times more frequently with mesalamine than sulfasalazine.[216] In a retrospective study, inflammatory bowel disease patients who received mesalamine and sulfasalazine did not show an increased risk of pancreatitis.[217]

Cisplatin, cytarabine, ifosfamide, paclitaxel, docetaxel, oxaliplatin, capecitabine, and the vinca alkaloids have been associated with pancreatitis, but the incidence is unknown.[218-242] Many cases of drug-induced pancreatitis have been reported during concurrent cytarabine and L-asparaginase administration. In one study, pancreatitis developed within 10 days of cytarabine and recurred with a rechallenge.[224] The lack of data from case-control studies or population-based studies makes it difficult to estimate the incidence of pancreatitis associated with these chemotherapeutic agents.[11]

In the 1950s, corticosteroids became the first drugs to be implicated in drug-induced pancreatitis. Steroids and adrenocorticotropic hormone (ACTH) accounted for 45.5% of the cases of reported drug-induced pancreatitis in the literature as of 1977.[171] Recurrences of pancreatitis have been reported following patients' re-exposure to steroids, including cases in which patients received intra-articular corticosteroid injections.[243,244] A population-based case-control study demonstrated an increased risk of acute pancreatitis in patients receiving oral glucocorticoids and suggested the risk is highest 4–14 days after the drug is dispensed.[245]

In 1963, the first case of sulfonamide-induced pancreatitis was reported.[246] More recently, there have been three reported cases of pancreatitis secondary to trimethoprim–sulfamethoxazole in which the disease developed within 5 days to 10 weeks after the initiation of therapy.[23,203,247-249]

Tetracycline-induced pancreatitis has been reported in patients with and without underlying liver disease.[250-256] Two reports of minocycline-induced pancreatitis and two reports of doxycycline-induced pancreatitis have been published.[257-260] A population-based case-control study identified a 60% increased risk of acute pancreatitis among current users of tetracycline antibiotics with doxycycline being the most commonly prescribed.[261] Tigecycline, an agent related to the tetracyclines, has been implicated in drug-induced pancreatitis in four case reports with the onset ranging from 7 to 14 days.[262-266] A retrospective cohort study of the U.S. Food and Drug Administration (FDA) Adverse Event Reporting System (FAERS) identified 62 cases of tigecycline-associated pancreatitis with females being at higher risk.[267]

A number of cases—the majority in the HIV/AIDS population—of aerosolized and injectable pentamidine-induced pancreatitis have been documented, including a report of recurrence after rechallenge.[23,268-283] Pancreatitis secondary to pentamidine typically occurs in the second week of treatment and resolves within 10 days after discontinuation, although there have been some reports of persistent pancreatitis following discontinuation. This may be explained by the lipophilic properties of pentamidine and/or a cumulative dose effect on the pancreas.[274,276] In a report of five cases of pentamidine-induced pancreatitis, all patients experienced episodes of hypo- or hyperglycemia, and four of the five also developed sepsis.[276] Glucose abnormalities, renal insufficiency, nonspecific abdominal pain, and nausea/vomiting after initiation of pentamidine may be early warning signs of pancreatitis.[268]

At least one case report supports a probable association between pancreatitis and ampicillin.[284] The patient developed pancreatitis 6 days after initiation of therapy, recovered 5 days after discontinuation, and relapsed 4 days after ampicillin therapy was reinstituted.

One case report of ciprofloxacin, potentially involving recurrent episodes 18 months apart, has been published.[285] In a single-center study, 3.1% of patients developed acute pancreatitis within an average of 5.5 days of receiving ciprofloxacin.[286]

Isoniazid-induced pancreatitis has been reported in 12 cases, eight of which were confirmed by rechallenge.[287-298] Isoniazid-associated acute pancreatitis typically has a median onset of 16 days after starting therapy and consistently recurs earlier, with a median onset of 9.4 days after rechallenge.[288]

The incidence of methyldopa-induced pancreatitis is unknown. Symptoms of methyldopa-induced pancreatitis generally occur within 1 week after initiation of therapy.[299-302] Patients typically recover without sequelae; however, a patient in one report developed chronic pancreatitis.[5,302]

There are numerous reports of estrogen-induced pancreatitis (with and without concomitant progesterone therapy).[303-309] Estrogen-induced pancreatitis begins 2–78 weeks after the initiation of therapy, and symptoms usually resolve approximately 10 days after discontinuation of estrogen.[23] Additionally, there is at least one case report of clomiphene (an estrogen agonist/antagonist) -induced pancreatitis in the literature.[310] Despite the case reports of estrogen-induced pancreatitis, a population-based case-control study did not find an association between pancreatitis and postmenopausal hormone therapy.[311] However, a retrospective study of 70 women found that estrogen use was associated with increased risk of pancreatitis.[312]

Several cases of furosemide-induced pancreatitis have been reported.[313-320] Doses ranged from 40 mg to 1,000 mg daily, and symptoms typically occurred within 2–5 weeks after initiation of therapy.[23] Additionally, other loop diuretics (bumetanide and ethacrynic acid) have been associated with pancreatitis.[317,321,322]

Chlorothiazide, hydrochlorothiazide, and chlorothalidone have all been reported to cause pancreatitis, which has developed from 2 weeks up to 1 year or more after initiation of therapy.[323-337]

Acute pancreatitis associated with valproic acid was first recognized in 1979, and since then there have been many case reports involving both adults and children.[338-374] The estimated incidence is one in 40,000.[375] The onset of pancreatitis with valproic acid may occur as early as 1 week or as long as several years after therapy has been initiated, although it most commonly occurs during the first year of therapy.[359] In a retrospective case-controlled trial, the risk of pancreatitis with valproic acid was similar to the risk with other antiepileptic agents.[376] Valproic acid-induced pancreatitis is more common in patients requiring higher doses, those receiving polytherapy, and those with chronic encephalopathies or on hemodialysis.[373] Fatalities secondary to valproic acid-induced pancreatitis in children have been reported.[377]

There are at least five case reports of drug-induced pancreatitis associated with carbamazepine.[378-382] In one of the reports, an initial episode of pancreatitis occurred 6 weeks after initiating therapy with carbamazepine, resolved when carbamazepine was discontinued, and recurred within 48 hours of a rechallenge.[379]

There are at least seven case reports of drug-induced pancreatitis with clozapine.[383-389] In two of these reports, pancreatitis resolved when the drug was withdrawn and recurred when therapy was reinitiated.[385,388] Other reports describe a syndrome of “asymptomatic pancreatitis” (characterized by hyperamylasemia) and eosinophilia induced by clozapine (although asymptomatic hyperamylasemia is usually not considered diagnostic for pancreatitis).[390,391]

There are at least eight reports of acute pancreatitis associated with tamoxifen.[392-399] Five reports noted that patients had a history of dyslipidemia.[393-395,397,398] Because hypertriglyceridemia is associated with pancreatitis, tamoxifen’s effect on triglycerides may contribute to pancreatitis risk. In one report, a patient who experienced pancreatitis while receiving tamoxifen alone was restarted on tamoxifen with a concomitant fibrate and did not experience recurrence during 3 years of follow-up.[395] The development of pancreatitis is delayed and variable ranging from 4 to 24 months.

Reports have associated tyrosine kinase inhibitors, sorafenib, axitinib, sunitinib, and nilotinib with drug-induced pancreatitis.[400-408] One report describes a patient who experienced acute pancreatitis 10 days after initiating sorafenib therapy.[400] After the drug was discontinued and the patient recovered from the acute episode, therapy with sunitinib was initiated. The patient remained on sunitinib without recurrence of pancreatitis for 20 months before being lost to follow-up.[400]

There are at least four case reports of patients experiencing drug-induced pancreatitis within 2–7 days after receiving bortezomib.[409-412] In two of these cases, rechallenge resulted in recurrence within hours.[411,412]

Pancreatitis has been reported to develop 2 weeks after administration of vermurafenib with recurrence following rechallenge.[413] In an open-label, multicenter study of 3,222 patients, three patients developed pancreatitis judged to be caused by vemurafenib.[414] In 2015, Health Canada approved updated labeling for vemurafenib to include a warning regarding the risk of pancreatitis.[415] The agency further reported that the cases generally occurred in the first 2 weeks of treatment.

There are at least nine reports of pancreatitis associated with brentuximab vedotin in the literature.[416,417] Two fatalities were reported as a result of progressive multiorgan dysfunction as a consequence of pancreatitis.[417] The median time to onset of pancreatitis was 26 days from initiation of therapy and 12 days from the most recent dose, with all cases occurring by the third cycle of therapy. One of three patients rechallenged with brentuximab vedotin experienced a recurrent episode of pancreatitis.[416,417] In one case, an additional six cycles of therapy were administered without recurrence.[416]

Case reports have associated pancreatitis with interferon alfa, both the standard and pegylated preparations, when used as monotherapy and in combination with ribavirin.[418-425] Two of these case reports describe recurrence of pancreatitis after rechallenge with interferon alfa-2b.[419] A retrospective review of 1,706 chronic hepatitis C-infected patients treated with interferon-alfa and ribavirin found that acute pancreatitis occurred in seven patients after a median duration of therapy of 12 weeks.[426] Pancreatitis resolved rapidly in all seven patients, and none had recurrent pancreatitis during a median follow-up of 18 months. The package inserts for pegylated interferon alfa-2a, pegylated interferon alfa-2b, and ribavirin contain warnings about the risk of pancreatitis and advise withholding or discontinuing therapy in cases of suspected pancreatitis.[427-429] The package inserts for both pegylated interferon formulations note that pancreatitis, including fatal cases, has been observed.[427,428]

Although there are numerous reports of drug-induced pancreatitis associated with the incretin-based therapies including the glucagon-like peptide 1 (GLP-1) receptor agonists and the dipeptidyl peptidase 4 (DPP-4) inhibitors used to treat type 2 diabetes mellitus, the association is controversial due to conflicting published information and because patients with type 2 diabetes mellitus have up to a threefold higher risk of developing acute pancreatitis compared to nondiabetic contols.[430]

There are at least 19 case reports in the literature of pancreatitis associated with incretin-based therapies.[431-448] In 2007 and 2008, the FDA issued alerts concerning postmarketing reports of 30 cases of acute pancreatitis and six cases of hemorrhagic or necrotizing pancreatitis in patients taking exenatide.[449] In 2009, the FDA issued an alert regarding 88 cases of acute pancreatitis including two cases of hemorrhagic or necrotizing pancreatitis in patients taking sitagliptin. As a result, the FDA encouraged manufacturers to warn about the risk of pancreatitis.[450-452]

In one analysis of reports in the FAERS, pancreatitis was found to occur greater than six times more frequently in patients receiving exenatide (OR 10.68, 95% CI 7.75–15.1, $p < 10^{-16}$) or sitagliptin (OR 6.74, 95% CI 4.61–10.0, $p < 10^{-16}$) than those receiving other antidiabetic therapies.[453] The Institute for Safe Medication Practices conducted another analysis of the FAERS data and also reported an increased risk with incretin-based therapies compared to other antidiabetic agents used to treat type 2 diabetes.[454] An analysis of the Italian Spontaneous ADR (adverse drug reaction) database likewise noted a higher incidence of pancreatitis associated with incretin-based therapies compared to other hypoglycemic agents (excluding insulin).[455] Conversely, at least 12 observational studies of data extracted from large insurance claims databases and national registries conducted to date failed to identify an increased risk of pancreatitis associated with the use of incretin-based therapies, and multiple meta-analyses have assessed the available literature and not identified an increased risk of pancreatitis associated with incretin-based therapies compared to control populations receiving placebo or other antidiabetic therapies.[430,456-476]

A population-based matched case-control study using a large administrative database in the United States found that the risk of hospitalization for acute pancreatitis was increased with current or recent past exposure to exenatide or sitagliptin.[477] Three large randomized controlled studies evaluated pancreatitis as a safety outcome in more than 18,000 patients exposed to the DPP-4 inhibitors saxagliptin, alopgliptin, and sitagliptin.[478-480] These studies showed that cases of acute pancreatitis were rare; however, they generally occurred more often in the exposed groups, but the differences were not significant. In a 56-week trial of 3,731 patients without type 2 diabetes, 0.4 pancreatitis events per 100 patient/years at risk was reported in the liraglutide group and <0.1 pancreatitis events per 100 patient/years at risk was reported in the placebo group.[481] There is the potential for confounding factors, including the presence of gallstones in 55% of the cases.

In 2014, FDA and the European Medicines Agency released a joint report that causal association between incretin-based drugs and pancreatitis is inconsistent with the current data; however, a final conclusion had not been reached.[482]

Notwithstanding this joint report, pancreatitis will continue to be considered a risk associated with these drugs and that risk is reflected in the current product information and labeling. All incretin-based therapies currently on the market contain warnings pertaining to pancreatitis, recommend immediate discontinuation of treatment when pancreatitis is suspected, and cautious use (or use of alternative therapy) in patients with a history of pancreatitis.[451,452]

There are isolated reports of amiodarone-induced pancreatitis.[483-485] A recent nested case-control study using a large database of U.S. health insurance claims found an association between amiodarone (but not other antiarrhythmic agents) and increased risk of acute pancreatitis in patients treated for nonvalvular atrial fibrillation.[486] The greatest risk was detected in the first 12 months after therapy was initiated.

There are at least four case reports of pancreatitis induced by the thioamide drugs methimazole and carbimazole, a prodrug of methimazole available outside of the United States.[487-490] All cases reported onset of symptoms within the first month of therapy. Rechallenge was attempted in three cases and recurrence of symptoms with an onset within 24 hours was noted each time.[487,489,490] In two of the four reports, the patients presented with concomitant mild cholestatic hepatitis, and in one of the cases the patient was further diagnosed with erythema nodosum.[488,489]

MECHANISMS

Drugs may induce pancreatitis through several possible mechanisms, including pancreatic duct hypertension secondary to intraluminal or extraluminal duct blockage and increased viscosity of pancreatic fluid leading to peripheral duct rupture and proenzyme release.[3] In addition, animal data have shown that reduced exocytosis and premature fusion of zymogen granules to lysosomes in pancreatic exocrine cells may activate pancreatic proenzymes and lead to cellular autodigestion. Drugs could play a role in this process. Predisposition to infection through immunosuppression may also be involved in pancreatitis caused by drugs such as corticosteroids and other immunosuppressants.[3] **Table 39-2** lists additional mechanisms that have been proposed for drugs known to be associated with pancreatitis.

ANTIMICROBIAL AGENTS

Metronidazole-induced pancreatitis may occur as a result of a redox cycling reaction that occurs under aerobic conditions and yields hydrogen peroxide and other oxygen-free radicals.[81,83,84,491,492] These redox active compounds are toxic to pancreatic β-cells and cause pancreatitis in animal models. Other suggested mechanisms for metronidazole-induced pancreatitis include an immune-mediated inflammatory response, pancreatic duct constriction, and metabolic effects.[81,83] The mechanism of tetracycline-induced pancreatitis is not completely understood; however, it may be related to a toxic metabolite of tetracycline, tetracycline-induced hypertriglyceridemia, or a high biliary concentration.[261,264,265,493] The precise mechanism of pentamidine-induced pancreatitis is not known, but animal studies suggest a direct toxic effect on the pancreas.[494] Pentamidine is known to cause both hypoglycemia and hyperglycemia, which is possibly due to damaged pancreatic β-cells.[23]

ESTROGEN

A possible mechanism of estrogen-induced pancreatitis is hyperlipidemia, a well-known cause of pancreatitis. Glueck et al. reported that 12 of 31 women with hypertriglyceridemia were receiving estrogen replacement therapy, and four of these 12 developed pancreatitis.[303] However, patients without elevated serum lipid concentrations receiving estrogens have also developed pancreatitis, suggesting that hypertriglyceridemia may not be the only factor in estrogen-induced pancreatitis.[304] Another proposed mechanism involves pancreatic necrosis induced by a hypercoagulable state.[101]

Table 39-2 Mechanisms of Drug-Induced Pancreatitis

Drug	Mechanism(s)
ACE inhibitors (captopril, enalapril lisinopril)	Bradykinin-induced inflammation; autoantibodies
5-acetylsalicylic acid	Immune-mediated reaction
Asparginase	Inhibition of protein synthesis through the hydrolysis of the amino acid L-asparagine
Azathioprine/6-mercaptopurine (MP)	Allergic reaction (type II or type IV to 6MP) and/or direct toxic effect
Brentuximab vedotin	Potentially unintended targeting of low-level pancreatic CD30
Codeine	Unknown (potentially constriction of the sphincter of Oddi)
Didanosine	Hypersensitivity or mitochondrial toxicity
Erythromycin	May cause spasm of the sphincter of Oddi, leading to abrupt pancreatic-duct hypertension and pancreatitis
Estrogen	Unknown (potentially hyperlipidemia or pancreatic necrosis induced by a hypercoagulable state)
Furosemide	Direct toxic effect, diuretic-induced pancreatic stimulation, hypersensitivity from an immunologic response against a drug-protein adduct, and/or ischemia related to impaired pancreatic blood flow due to volume contraction

Hydrochlorothiazide	Increased serum calcium leads to calculi in the pancreatic ducts; direct toxic effect secondary to increased parathyroid hormone levels or increased calcium levels may accelerate the conversion of trypsinogen to trypsin causing pancreatitis; and/or thiazides lead to hypotension and pancreatic ischemia
Interferon α	Unknown (potentially immune system stimulation leading to autoimmune destruction of the pancreas)
Isoniazid	Unknown (potentially hypersensitivity)
Methyldopa	Unknown
Metronidazole	Undergoes redox cycling reaction yielding hydrogen peroxide and other oxygen-free radicals—toxic to pancreas Other suggested mechanisms: immune-mediated inflammatory response, pancreatic duct constriction, metabolic effects
Pentamidine	Direct toxic effect on the pancreas
Statins (atorvastatin, fluvastatin, lovastatin, pravastatin, simvastatin)	Immune-mediated inflammatory response, metabolic effect, or direct cellular toxicity Other suspected mechanisms: associated with rhabdomyolysis, myalgia, and/or metabolism or drug interactions through cytochrome P-450 3A4
Sulfonamide (sulfamethoxazole)	Hypersensitivity
Sulindac	Hypersensitivity
Tamoxifen	Increased triglycerides, cytotoxic injury
Tetracycline	Unknown (potentially toxic metabolite, hypertriglyceridemia, high biliary concentration)
Tyrosine kinase inhibitors	Effects on vascular endothelial growth factor; decreased gastrointestinal motility
Valproic acid	Hypersensitivity
Vemurafenib	Possibly induces proliferation of cells leading to obstructive pancreatitis

THIAZIDE DIURETICS

Thiazides may have a direct toxic effect on the pancreas.[324] Additionally, thiazides are known to cause hypercalcemia and hypophosphatemia, conditions present in patients with primary hyperparathyroidism, which is a disease known to increase the risk of pancreatitis.[323] Increased serum concentrations of parathyroid hormone may be present in patients treated with thiazide diuretics and can result in pancreatitis.[324,325] Additionally, elevated serum calcium concentrations may lead to calculi within the pancreatic ducts and/or may accelerate the conversion of trypsinogen to trypsin, causing pancreatitis.[495] It has also been suggested that thiazides may cause pancreatitis as a result of thiazide-induced hyperlipidemia[325] or that thiazide-induced reductions in blood pressure may lead to pancreatic ischemia.[1]

ANTI-INFLAMMATORY AGENTS

Sulfasalazine-induced pancreatitis may occur due to an immune-mediated or allergic reaction.[496,497]

VALPROIC ACID

Pancreatitis associated with valproic acid may be related to a hypersensitivity reaction and recurs after rechallenge with the drug.[338-342] It has been theorized that valproic acid may cause depletion of the free-radical scavengers superoxide dismutase (SOD), catalase (CAT), and glutathione peroxidase, resulting in an excess of free radicals that may promote endothelial permeability and lipid peroxidation, ultimately leading to tissue damage.[498-500]

L-ASPARAGINASE

L-asparaginase–induced pancreatitis may occur as a result of inhibition of protein synthesis through hydrolysis of the amino acid L-asparagine.[166,501-503] Organs with high protein synthesis rates, such as the liver and pancreas, are more severely affected. The presence of glutaminase or an endotoxin cannot be excluded as a mechanism because L-asparaginase is extracted from *Escherichia coli*.[504,505] Genetic predispositions are likely to play a role.

ACE INHIBITORS

ACE inhibitors increase serum bradykinin concentrations, and bradykinin acts as a mediator of inflammation that may lead to localized angioedema and obstruction of pancreatic ducts.[101,506] Bradykinin has also been found to increase vascular permeability in early-stage pancreatitis induced by cerulein.[507] Bradykinin antagonists such as HOE-140 have been shown to have a protective role in pancreatitis.[508] Drugs may cause local pancreatic angioedema, obstructing the pancreatic duct and causing enzymes and other toxic substances to be trapped within the pancreas. This leads to tissue damage and is a likely cause of acute pancreatitis that occurs rapidly after drug initiation.[101,509] Other possible mechanisms are ACE inhibitor-induced hypoglycemia resulting in toxic effects on the pancreas and the effects of combined toxins, including ACE inhibitors and alcohol.[46,510,511]

Animal studies suggest that ACE inhibitors may increase pancreatic secretion as a possible or contributing mechanism.[47] Another theory is that ACE inhibitors induce the formation of autoantibodies, which then attack pancreatic cells.[46] Both captopril and enalapril have been found to induce the production of autoantibodies in many tissues, including the pancreas.[512]

CLOZAPINE

The mechanism by which clozapine induces acute pancreatitis is unknown. Clozapine may have exocrine and possibly toxic effects on the pancreatic and salivary tissues, or clozapine-induced pancreatitis may occur as a result of an allergic reaction.[384,385]

HISTAMINE-2 (H_2) RECEPTOR ANTAGONISTS

This class of drugs may affect pancreatic secretory stimuli through reduction of gastric and duodenal acidity and/or may cause pancreatitis through an idiosyncratic reaction.[3,68]

NSAIDs AND ACETYLSALICYLIC ACID

The probable mechanism of acetylsalicylic acid (ASA)- or NSAID-related pancreatitis is inhibition of prostaglandins that may cause pancreatic duct constriction.[3,513] Aspirin has been shown to increase pancreatic duct permeability in animals.[514,515] Administration of intravenous aspirin increases calcium secretion from the pancreas, which is considered a marker of pancreatic damage.[516] Experimental studies suggest that prostaglandins may have a protective effect on pancreatic cells. Administration of prostaglandin E_2 in a mouse model of experimental pancreatitis was associated with an improved survival rate compared with the 100% mortality reported in controls. Membrane stabilization of pancreatic cells may be the mechanism behind the cytoprotection conferred by prostaglandins.[517] A proposed mechanism for sulindac-induced pancreatitis is metabolite deposition in biliary epithelial cells and inhibition of canalicular bile transport, leading to hypercholoresis.[66]

CALCIUM

It is possible that hypercalcemia induces chronic pancreatic exocrine secretion changes that may affect ductal epithelium.[171] Intracellular calcium in pancreatic zymogen granules is important in the maintenance of granule stability, and factors disrupting this delicate balance may contribute to calcium-induced pancreatitis.[518]

CORTICOSTEROIDS

Corticosteroids may induce pancreatitis through toxic effects, immune suppression, or increased viscosity of pancreatic fluids.[171] The viscosity of pancreatic secretions was greater in steroid-treated glands in an ex vivo study of perfused canine pancreas exposed to high doses of methylprednisolone.[519] Steroids stimulate both exocrine and endocrine pancreatic secretions, which may contribute to the development of drug-induced pancreatitis.[520]

STATINS

The exact mechanism of statin-induced pancreatitis is unclear. Some hypothesized mechanisms include immune-mediated inflammatory response, a metabolic effect, and direct cellular toxicity.[88] The propensity of the statins to cause pancreatitis may differ based on their inhibitory effects on cytochrome P450 and their lipophilicity. Other possible mechanisms of statin-induced acute pancreatitis involve rhabdomyolysis and drug interactions or changes in metabolism that may alter the pharmacokinetics of the agents.[101]

TYROSINE KINASE INHIBITORS

The mechanism of tyrosine kinase inhibitor-induced acute pancreatitis is not well understood, but possible explanations include effects on vascular endothelial growth factor (VEGF) and gastrointestinal motility.[400,403] The inhibition of VEGF may cause ischemia of the pancreatic tissue, increasing the risk of pancreatitis.[521] VEGF may also play a role in regulating the cell cycle of acinar cells; therefore, inhibition of VEGF may lead to acinar cell apoptosis and the release of autodigestive enzymes.[400,403] Tyrosine kinase inhibitors may decrease gastrointestinal motility, leading to reflux of the duodenal contents into the pancreatic duct and premature activation of pancreatic acinar cell digestive enzymes, leading to autodigestion.[400,403]

TAMOXIFEN

The exact mechanism for tamoxifen-induced pancreatitis is unclear but may be related to increased synthesis of triglycerides, leading to the presence of numerous chylomicrons in the blood that may obstruct capillaries, leading to pancreatic ischemia. Additionally, the degradation of triglycerides to free fatty acids by pancreatic lipases may lead to cytotoxic injuries that increase inflammatory mediators.[392]

INCRETIN-BASED THERAPIES

The mechanism of pancreatitis induced by incretin-based therapies is unknown. One theoretical model has proposed that the agents could have effects on the exocrine pancreas resulting in amplification of pancreatic ductal replication. This could lead to overgrowth of cells lining the smaller ducts and a resultant partial obstruction, which increases the risk for low-grade pancreatitis and may predispose the patient to acute pancreatitis.[472]

THIOAMIDES

The mechanism of thioamide-induced pancreatitis is unknown and hypersensitivity reactions, direct toxic effects, and autoimmune reactions have all been considered.[487] The development of pancreatitis within 1 month of therapy initiation and rapid recurrence with rechallenge supports a hypersensitivity mechanism possibly due to the sulfhydryl group.[488-490]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The clinical presentation of drug-induced pancreatitis is similar to that of acute pancreatitis secondary to other causes.[3] **Table 39-3** summarizes the usual signs and symptoms associated with drug-induced pancreatitis. Typically, patients with acute pancreatitis present with abdominal pain, nausea, vomiting, abdominal distention, and low-grade fever. The presentation may also include pain that radiates to the back, hypotension, mental aberrations, and jaundice. Complications may include the development of pancreatic abscess, pseudocyst formation, and the development of subcutaneous fat necrosis and bluish discoloration of the abdominal wall.[522]

Table 39-3 Signs and Symptoms Associated with Drug-Induced Pancreatitis[1]

- Abdominal distention (75%)
- Abdominal pain (95%)
- Hypotension (30%)
- Jaundice (20%)
- Low-grade fever (75%)
- Mental aberrations (25%)
- Nausea/vomiting (80%)
- Pain radiating to back (50%)

Diagnosis is usually based on clinical and laboratory data. Laboratory parameter abnormalities that may occur in patients with drug-induced pancreatitis include leukocytosis, hyperglycemia, hypoalbuminemia, mild hyperbilirubinemia, elevated blood urea nitrogen and serum creatinine concentrations, elevated hemoglobin, elevated hematocrit, hypocalcemia, thrombocytopenia, and prolongation of prothrombin time and international normalized ratio (INR).[1] Serum amylase concentrations usually increase within 24 hours of the onset of symptoms and will return to normal over a period of several days. Persistent elevation in serum amylase concentrations is suggestive of extensive pancreatic necrosis and/or related complications. Serum amylase concentrations do not correlate with severity of disease or etiology. In contrast, lipase originates in the pancreas, making it a more specific marker for pancreatitis than serum amylase. Elevations in serum lipase concentrations persist longer than those of serum amylase concentrations. Imaging techniques such as ultrasound may be indicated in patients with suspected biliary involvement. Contrast-enhanced computerized tomography (CECT) may be useful in determining severity of the inflammatory process, and it also provides an estimate of risk for systemic and local complications.[523,524] Some literature has asserted that a mean peak C-reactive protein value is significantly lower in drug-induced acute pancreatitis than in pancreatitis from other causes; therefore, careful search for an adverse drug reaction is appropriate in patients with acute pancreatitis of unknown cause and a low peak C-reactive protein level.[525]

As the clinical presentation of drug-induced pancreatitis is similar to that of pancreatitis due to other causes, drug-induced pancreatitis is usually diagnosed after other more common etiologies have been ruled out. A careful medication history including prescription and nonprescription medications as well as herbal supplements should always be done and will be helpful in differential diagnosis. Most commonly, acute pancreatitis occurs secondary to alcohol ingestion or cholelithiasis. Less common etiologies include abdominal trauma, toxins, hyperlipidemia, pancreatic tumor, complications of surgery, infection, and vascular abnormalities.[526] Endoscopic retrograde cholangiopancreatography (ERCP), which is used to diagnose pancreatitis, can also, ironically, cause pancreatitis in up to 40% of patients who undergo the procedure.[527] A recent single-center cohort of 318 patients undergoing ERCP procedures evaluated risk factors for post-ERCP pancreatitis and found that use of Badalov Class I or II drugs during the prior month was associated with an increased risk of post-ERCP pancreatitis.[528] **Table 39-4** lists conditions to consider in the differential diagnosis of drug-induced pancreatitis.

Table 39-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Pancreatitis[526]

- Abdominal trauma
- Cholelithiasis
- Drugs
- Endoscopic retrograde cholangiopancretography
- Hyperlipidemia
- Infection
- Pancreatic tumor
- Surgery
- Toxins

With drug-induced pancreatitis, the time from initiation of therapy to the onset of pancreatitis symptoms varies depending on the causative drug. No generalizations can be made, and for most drugs, pancreatitis can occur from within a short time after administration of the first dose to years after therapy begins.

RISK FACTORS

Risk factors for drug-induced pancreatitis are presented in **Table 39-5**. Any disease state that predisposes patients to hypercalcemia, such as hyperparathyroidism, malignancy, thyrotoxicosis, or multiple myeloma, as well as circumstances such as hard-water syndrome, tumor lysis syndrome, and cholecalciferol overdose increase the risk of drug-induced pancreatitis.[230,529-534] In addition, the risk for drug-induced pancreatitis is increased in patients receiving a drug with a definite or probable association with pancreatitis for management of a disease state that is also independently associated with pancreatitis.[535] For example, immunosuppression increases the risk of infection, infectious processes are often associated with pancreatitis, and patients with disease states associated with immunosuppression, such as renal transplantation or HIV/AIDS, have an increased incidence of drug-induced pancreatitis.[3] Autoimmune diseases such as inflammatory bowel disease have also been linked to pancreatitis, and patients with these conditions are at increased risk of developing drug-induced pancreatitis when treated with drugs that have definite or probable associations with the disease.[9,536]

Table 39-5 Risk Factors for Drug-Induced Pancreatitis

- Autoimmune disease
    - Crohn disease
- Drug-induced
    - Idiosyncratic reaction—large number of risk factors are unknown
- Female sex
- Hypercalcemia
    - Cholecalciferol overdose
    - Hard-water syndrome
    - Hyperparathyroidism

    - Malignancy
    - Multiple myeloma
    - Thyrotoxicosis
    - Tumor lysis syndrome
- Hyperlipidemias
    - Concurrent estrogen therapy
- Immunosuppression
    - HIV/AIDS
    - Renal transplantation
- Pediatric patients

AIDS = acquired immunodeficiency syndrome, HIV = human immunodeficiency virus.

Specific risk factors for didanosine-associated pancreatitis in the AIDS population have been identified. These include severity of HIV disease (CD4 count <200 cells/µL), didanosine dose >9.6 mg/kg/d, drug-related hyperlipidemia, therapy >10 weeks in duration, previous history of pancreatitis, concomitant alcohol use, and concomitant use of pentamidine.[20,25,537] Additionally, concomitant use of other drugs known to cause pancreatitis, particularly pentamidine, hydroxyurea, or stavudine increases the risk of didanosine-induced pancreatitis.[32,33,35] Ribavirin should be used with extreme caution in patients receiving didanosine due to the risk of fatal lactic acidosis and pancreatitis.[37] Previous exposure to didanosine is a risk factor for developing pentamidine-induced pancreatitis.[282]

MORBIDITY AND MORTALITY

Drug-induced pancreatitis may be mild to severe. The majority of patients recover without any long-term morbidity, but 5–15% of patients experience life-threatening complications, with a majority of severe complications occurring within 48 hours of onset.[3] Approximately 3–13% of acute pancreatitis cases develop into chronic pancreatitis.[101] A retrospective study including data from 43 German centers of gastroenterology found that the majority of drug-induced pancreatitis cases run a benign course; no patients experienced pseudocyst development or required mechanical ventilation.[9] However, the mean hospital stay was 25.5 days. Of all cases of suspected drug-induced pancreatitis reported to the Danish Committee on Adverse Drug Reactions from 1968 to 1999, 68% required hospitalization for treatment, with a 9% mortality rate.[6] Another Dutch study reported a 15% mortality rate associated with drug-induced pancreatitis.[68]

Ranson's criteria may be used to assess the severity of an episode of drug-induced pancreatitis and may be used to predict mortality (**Table 39-6**).[101,522] The presence of three or more of these criteria indicates a more severe disease with a higher risk of mortality. Severe acute pancreatitis is associated with an Acute Physiology and Chronic Health Status Evaluation (APACHE) score >8, associated organ failure, or >30% pancreatic necrosis viewed on computerized tomography scan, and with a Ranson's score >3.[537] There have been fatalities in case reports of pancreatitis associated with many drugs, with a seemingly higher incidence of mortality in patients with pancreatitis due to azathioprine, didanosine, furosemide, or hydrochlorothiazide. Many fatal cases with azathioprine occur after renal transplantation, and most didanosine-related cases occur in AIDS patients, in which the incidence of pancreatitis is greater.[9] In severe cases, circulatory, pulmonary, and renal complications may occur and ultimately result in death.[522]

Table 39-6 Severity of Pancreatitis Based on Ranson's Criteria[101,522]

At Hospital Admission or Diagnosis[a]	During First 48 Hours After Admission or Diagnosis[a]
• Age >55 years	• Fall in hematocrit of >10% (absolute %)
• WBC >16,000 cells/mm^3	• Rise in BUN of >5 mg/dL
• Blood glucose >200 mg/dL	• Serum calcium <8 mg/dL
• Serum LDH >350 units/L	• Arterial oxygen pressure of <60 mm Hg
• Serum aspartate aminotransferase >250 units/dL	• Base deficit of >4 mEq/L • Estimated fluid sequestration of >6 L

BUN = blood urea nitrogen, LDH = lactic dehydrogenase, WBC = white blood cell.

[a] The presence of three or more of these criteria indicates a more severe disease with a higher risk of mortality.

Table 39-7 Approaches to Help Prevent Drug-Induced Pancreatitis

- Azathioprine, 6-mercaptopurine, mesalamine, corticosteroids, metronidazole for inflammatory bowel disease
  - For patients with abdominal pain, consider pancreatitis as part of the differential diagnosis
- Didanosine
  - Adjust dose for weight <60 kg
  - Avoid alcohol or other drugs that can cause pancreatitis
  - Avoid use with *Pneumocystis jiroveci* therapy
- Hypercalcemia
  - Treat underlying condition (hyperparathyroidism, malignancy, thyrotoxicosis)
- Immunosuppressive agents
  - Use lowest effective dose of immunosuppressive agents (tacrolimus, cyclosporine, sirolimus)

PREVENTION

Drug-induced pancreatitis is a relatively rare, idiosyncratic disease. It is important for clinicians to be aware of this potential adverse event and to consider medications as potentially causative when other etiologies of pancreatitis are not present. Prevention strategies for specific agents and drug categories are summarized in **Table 39-7**. Measurement of serum lipase and amylase concentrations should be performed in patients who develop abdominal discomfort and who are taking medications associated with pancreatitis.[44,281,390,537] Indications for monitoring serum amylase and lipase concentrations in the absence of symptoms are less clear. One group of authors suggests monitoring serum amylase and lipase in patients taking ACE inhibitors.[538] Some have recommended routine monitoring of serum amylase and lipase concentrations during mirtazapine treatment and, in particular, when upward dose adjustments are made. This recommendation, however, is based on only one confirmed case of pancreatitis and two other reports that describe only asymptomatic elevations in serum lipase and amylase concentrations.[539] Serial serum amylase concentration monitoring and sonograms are not helpful in making an early diagnosis of pancreatitis in patients receiving L-asparaginase therapy.[137,540-542] In patients with a pre-existing pancreatic disorder, L-asparaginase is contraindicated because of its well-known pancreatic toxicity.[543]

The National Institute of Allergy and Infectious Diseases recommends screening all patients for a history of pancreatitis before initiating therapy with didanosine. Patients taking didanosine should avoid alcohol and other drugs known to cause pancreatitis. Didanosine therapy should be discontinued during and for 1 week after treatment with pentamidine or sulfonamides for *Pneumocystis jiroveci* pneumonia. The dose of didanosine should be reduced from 400 mg to 250 mg in patients that weigh <60 kg.[37,39]

Clinical judgment should be used when deciding whether or not to monitor serum pancreatic enzyme concentrations. In most cases, routine monitoring of serum amylase and lipase concentrations is not warranted unless symptoms suggestive of pancreatitis develop. This is due to the low incidence of drug-induced pancreatitis and often asymptomatic (and thus clinically unimportant) hyperamylasemia that occurs in association with many drugs. If abdominal pain, nausea, and vomiting occur in patients being treated with drugs known to cause pancreatitis, prompt laboratory evaluation of serum pancreatic enzyme concentrations and other diagnostics should be initiated.

MANAGEMENT

If drug-induced pancreatitis is suspected, prompt discontinuation of the suspect agent is necessary. Traditional therapeutic management of pancreatitis should be initiated, including administration of intravenous fluids, administering nothing by mouth, advancing the diet as tolerated, and providing adequate analgesia.[3]

INFORMATION FOR PATIENTS

Patients taking medications with a definite or probable association with pancreatitis should be instructed to report the onset of acute abdominal pain to their healthcare provider immediately. Some clinicians recommend advising patients to immediately discontinue the suspected causative drug and seek medical attention if they experience abdominal pain, nausea, or vomiting. If possible, patients should avoid drugs that caused pancreatitis for them in the past.

CHAPTER 40

Nausea and Vomiting

Saeed K. Alzghari, Bonnie A. Labdi, and Jon D. Herrington

Nausea and vomiting account for the majority of medication-related gastrointestinal (GI) maladies.[1] Although any drug, including placebos, can potentially induce nausea and vomiting, some classes of medications are more likely to cause these effects than others.[2] Drug-induced nausea and vomiting can adversely affect quality of life, and patients who experience significant symptoms may stop taking the culprit drug as prescribed, thus compromising their own treatment. If therapy is continued, symptoms can become severe enough to interfere with normal daily activities, and, if left untreated, vomiting can lead to serious health risks, including esophageal tears and malnutrition, requiring additional medical attention.

Nausea is a subjective feeling and a singular symptom. It may or may not be followed by vomiting, although both are thought to be components of the same reflex.[3,4] The term itself is derived from the Greek word *naus*, meaning ship, alluding to the way one feels when seasick.[5] Nausea is most easily defined as an inclination to vomit, or the way one feels when vomiting is imminent.

Practically any drug can cause nausea, vomiting, or both via one of several mechanisms, and many can cause nausea and vomiting through a combination of mechanisms. Three classes of drugs known to cause nausea and vomiting in a significant percentage of patients—the opioids, the anesthetics and related drugs, and the chemotherapeutic agents—will be discussed in detail in this chapter. Other miscellaneous agents will be discussed where information exists.

CAUSATIVE AGENTS

Agents commonly associated with nausea and vomiting are listed in **Table 40-1**. References cited are from controlled trials of single agents administered without prophylactic antiemetics.[6-115] Because of the large number of agents reported to cause nausea and vomiting and wide interindividual variability, this list should not be regarded as comprehensive.

Table 40-1 Agents Implicated in Drug-Induced Nausea and Vomiting

Drug	Incidence	Level of Evidence[a]
OPIOIDS		
Alfentanil[6]	N = 19% V = 9%	A
Buprenorphine[7]	V = 20%	A
Butorphanol IV[8,9]	V = 14% N/V = 13%	A
Codeine[10,11]	N = 41% V = 24% N/V = 44%	A
Diamorphine[7]	V = 12%	A
Dihydrocodeine[12]	N = 15–27% V = 10–12%	A
Fentanyl IV[6,13]	N = 19–32% V = 10–20%	A
Hydrocodone[10]	N = 29% V = 10%	A
Hydromorphone[14]	N = 35% V = 17%	A
Meperidine[15]	N/V = 13%	B
Methadone[16]	N = 50% V = 24%	B
Morphine[13,17,18]	N = 20–52% V = 15–36%	A
Nalbuphine[18]	N = 4%	A

	V = 4%	
Oxycodone[14]	N = 30% V = 12%	A
Oxymorphone[19]	N = 39% V = 24%	A
Piritramide[17]	N = 30% V = 19%	A
Propoxyphene[11]	N/V = 38%	A
Remifentanil[13]	N = 20% V = 8%	A
Sufentanil[6]	N = 19% V = 7%	A

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials;

Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

OPIOIDS

All opioid receptor agonists may cause nausea and vomiting. In general, when compared at equianalgesic doses, opioids are similar in their likelihood to induce nausea and vomiting.[116,117]

PERIOPERATIVE AGENTS

The majority of the studies included in Table 40-1 are from randomized, placebo-controlled trials in which patients did not receive other agents known to be emetogenic or to possess antiemetic effects (e.g., propofol, ondansetron). For those that included multiple emetogenic agents, the groups were similar except for the study agent. In many postoperative nausea and vomiting (PONV) trials, patients receive a host of drugs for supportive care, making data interpretation challenging.

CHEMOTHERAPY

Emetogenicity varies between chemotherapy agents and can also depend on the number of agents administered on the same day. Whenever possible, references included in Table 40-1 represent reports in which patients received single agents without prophylactic antiemetic therapy.

EPIDEMIOLOGY

OPIOIDS

It has been estimated that 10–40% of ambulatory patients experience nausea and 15–40% experience vomiting on the initiation of opioid therapy.[118]

PERIOPERATIVE AGENTS

The overall incidence of PONV has been estimated to be 10–80%, depending on the number of patient-specific risk factors present, type of surgery, choice of anesthesia, and age and sex of the patient.[119-123]

CHEMOTHERAPY

The expected incidence of emesis associated with chemotherapy without the use of antiemetics is included in Table 40-1. In 1981, insight into chemotherapy-induced nausea and vomiting (CINV) was provided in a study of patients receiving high-dose cisplatin. Patients were randomly assigned to receive placebo (n = 10) or high-dose metoclopramide (n = 11).[51] In the high-dose metoclopramide group, a median of 1 emetic episode (range, 0–9) occurred in a 24-hour period as compared with 10.5 episodes (range, 5–25) in the placebo group. All placebo-treated patients vomited, as compared with 7 of 11 metoclopramide-treated patients. Although this was a small study, it helped to clearly demonstrate the necessity of prophylactic antiemetic therapy in patients receiving chemotherapy.

When antiemetic drugs (5-hydroxytryptamine-3 [5-HT_3] receptor antagonist plus dexamethasone) are administered before emetogenic chemotherapy, the incidence of vomiting varies from 20% to 75%, and the incidence of nausea is as high as 96%.[124] With the use of newer antiemetics, the presence of nausea is still problematic; however, the intensity of the nausea episodes has decreased.[125]

MISCELLANEOUS AGENTS

The expected incidence of nausea and vomiting associated with a variety of medication classes is listed in Table 40-1. As noted above, virtually any drug is capable of causing nausea or vomiting or both, and the list, therefore, is not exhaustive.

Some drugs cause nausea and vomiting when administered in normal therapeutic doses while with others nausea and vomiting can be a sign of toxicity. For example, nausea and vomiting is a classic finding in patients with digoxin toxicity. In a review of elderly patients with a mean digoxin serum concentration >6 ng/mL, 47% were found to have nausea and vomiting.[126]

MECHANISMS

The mechanisms of drug-induced nausea and vomiting are described in **Table 40-2**.[117,121,127-149] Nausea with or without subsequent vomiting is thought to be the result of a centrally controlled protective mechanism involving the GI tract.[4,5,127,148] The sensation of nausea and the act of vomiting serve to discourage the ingestion and/or absorption of toxic substances or to indicate that a portion of the GI tract is not functioning properly.[149,150] Nausea and vomiting may also occur during periods of stress secondary to decreased activity of the parasympathetic nervous system.[149]

Table 40-2 Mechanisms of Drug-Induced Nausea and Vomiting

Drugs	Mechanism
Bromocriptine[144]	• Causes CTZ stimulation by dopamine
Chemotherapy[135,136]	• Has direct CTZ stimulation by neurotransmitters (e.g., dopamine, serotonin, substance P, histamine, norepinephrine) • Damages GI mucosa and allows release of 5-HT_3, which stimulates the vagal afferent nerve and thus activates CTZ and emetic center, the nucleus tractus solitarius

	• Has indirect or direct effects on the cerebral cortex • Vestibular alterations • Causes taste and olfactory changes, which enhance the gag, nausea, and vomiting reflexes
Digoxin[144,145]	• Stimulates CTZ
Estrogens[145]	• Stimulate CTZ
Erythromycin[137-140]	• Motilin agonist • 5-HT_3, cholinergic agonist • Disruption of interdigestive migrating motor complex
GLP-1 receptor agonists[159]	• Increase glucose-dependent insulin secretion • Decrease glucagon secretion • Delay gastric emptying
Inhaled anesthetic agents[121,131-133]	• Stimulate CTZ • Cause afferent sensory input from higher cortical centers, the vestibular nucleus • Directly stimulate serotoninergic receptors in the GI tract
Levodopa[146]	• Causes CTZ stimulation by dopamine
Metronidazole[141–143]	• Causes taste alterations • Causes monoamine release
Neuromuscular-blocking agents[131]	• Block acetylcholine receptors in muscle
Nitrous oxide[131,132]	• Stimulates the release of dopamine in the medulla • Changes middle ear pressure, resulting in stimulation of the vestibular apparatus • Abdominal distention during mask ventilation, leading to direct activation of the nociceptors • Causes hypoxia, which has been correlated with PONV • Stimulates opioid receptors
Opioids[117,127–130]	• Stimulate CTZ • Decrease neural activity in the GI tract, leading to a decrease in motility and a decrease in pyloric tone • Increase vestibular sensitivity via histaminergic and muscarinic pathways
Serotonin reuptake inhibitors[147]	• Cause CTZ stimulation by serotonin
Spinal anesthesia[134]	• Blocks sympathetic nerves leading to an increase in vagal tone • Decreases in cerebral blood flow with subsequent hypoxia caused by reductions in blood pressure

5-HT_3 = 5-hydroxytryptamine$_3$, CTZ = chemoreceptor trigger zone, GI = gastrointestinal.

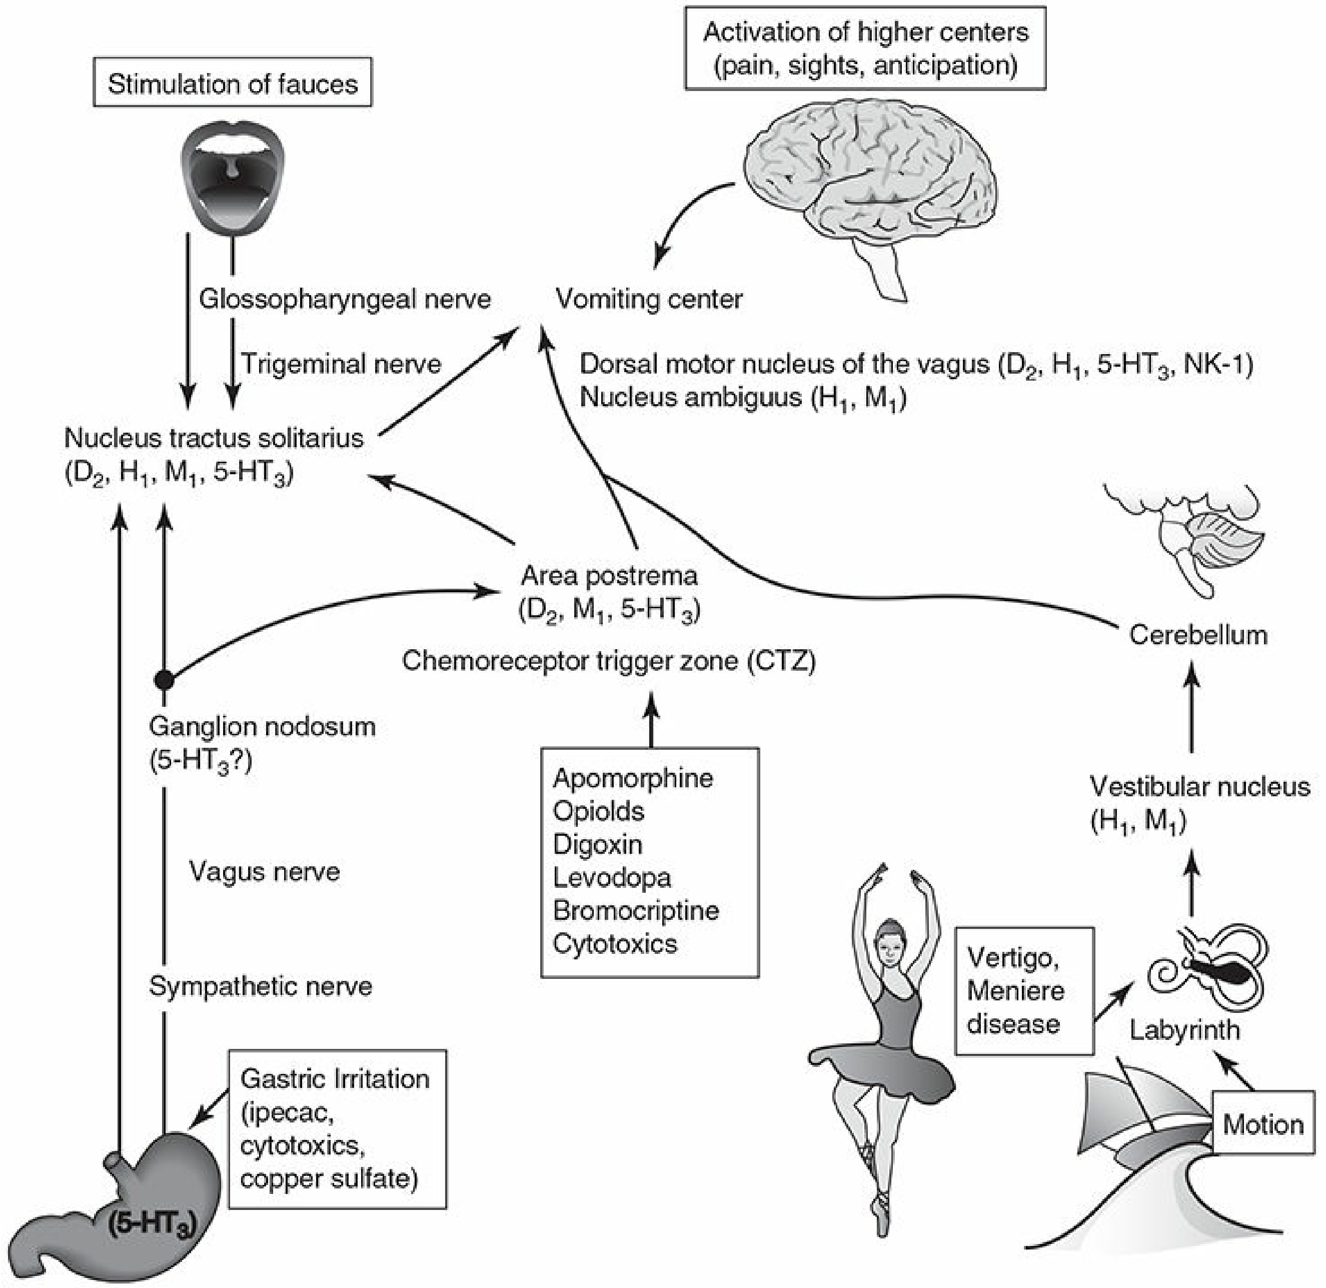
The signs and symptoms of nausea and vomiting can be quite dramatic and troublesome for any patient (**Table 40-3**). Emesis, or the act of vomiting, may be divided into three distinct phases: pre-ejection, ejection, and postejection.[148] Nausea, which often (but not always) precedes vomiting, is included in the pre-ejection phase and is often accompanied by other symptoms, such as pallor, salivation, shivering, tachycardia, and gastric stasis.[127,128,148,151] Retching marks the beginning of the ejection phase of emesis and involves the coordinated rhythmic contraction of the diaphragm, the abdominal muscles, and the external intercostal muscles.[3,127,148,152] During this phase, the glottis remains closed. With each retch, the esophageal pressure decreases while the intra-abdominal pressure increases. Emesis occurs when the contracting abdominal muscles cause an increase in esophageal pressure, forcing the glottis open and allowing the contents of the upper GI tract to be expelled.[127,148] Lethargy and muscle weakness mark the beginning of the postejection phase and are a direct result of emesis. Depending on the circumstances, an individual may experience additional episodes of retching or vomiting or both, and this cycle may be repeated several times.[148]

Table 40-3 Signs and Symptoms Associated with Drug-Induced Nausea and Vomiting

- Abdominal muscle contraction
- Confusion
- Deep breath
- Dizziness
- Feeling cold or hot
- Feeling sick
- Gastric stasis
- Loss of appetite
- Loss of taste
- Orthostatic hypotension
- Pallor
- Retching
- Salivation
- Sweating
- Tachycardia
- Vomiting

Nausea and vomiting are centrally mediated responses to the presence of chemicals, toxins, or stressors.[3,4,148-150] The vomiting center, located in the medulla, is thought to initiate the vomiting reflex after receiving afferent sensory input from other areas, including the GI tract, cerebral cortex, and the chemoreceptor trigger zone (CTZ).[127] The CTZ, the emetic or vomiting center, and the GI tract possess a variety of neurotransmitter receptors. The primary receptors involved with emesis are dopamine subtype 2 (D_2) and 5-HT_3 receptors. Other receptors thought to be involved in nausea and vomiting include the prostaglandin, opiate, cannabinoid, muscarine subtype 1 (M1), histamine subtype 1 (H1), and neurokinin (NK-1) receptors.[127,129] The CTZ can be stimulated by a wide variety of neurotransmitters, chemicals, and toxins found in the blood and in the cerebrospinal fluid.[129] Upon stimulation, the CTZ, located in the area postrema, sends afferent impulses to the vomiting center, nucleus tractus solitarius, which in turn sends efferent impulses to the respiratory and salivary centers, cranial nerves, and the abdominal muscles.[127]

Neuronal pathways originating in the GI tract can also directly activate the vomiting center.[151] Drugs or chemicals that irritate or damage the lining of the GI tract are thought to cause nausea and vomiting via these pathways.[128] In addition, the release of 5-HT_3 from the enterochromaffin cells located throughout the GI tract can induce vomiting via serotoninergic afferent pathways to the vomiting center.[129] **Figure 40-1** depicts the afferent pathways involved in the act of vomiting and nausea.[153]



Stimulation of fauces
Activation of higher centers (pain, sights, anticipation)
Glossopharyngeal nerve
Trigeminal nerve
Vomiting center
Dorsal motor nucleus of the vagus (D2, H1, 5-HT3, NK-1)
Nucleus ambiguus (H1, M1)
Nucleus tractus solitarius (D2, H1, M1, 5-HT3)
Area postrema (D2, M1, 5-HT3)
Chemoreceptor trigger zone (CTZ)
Cerebellum

Anticipatory nausea and vomiting are thought to be the result of afferent impulses originating in the cerebral cortex, whereas the nausea associated with motion sickness is attributed to stimulation of the vestibular apparatus.[128] Regardless of the origin of the stimulus, the end result is the same; the vomiting center initiates the act of emesis in response to afferent input.[129,151]

OPIOIDS

Opioids are thought to induce nausea and vomiting via several mechanisms. First, opioid analgesics stimulate the CTZ, resulting in activation of the vomiting center.[127,128] Second, opioids decrease neural activity in the GI tract, leading to a decrease in motility and a decrease in pyloric tone, both of which can induce nausea or vomiting or both.[117,130] Third, opioids are thought to increase vestibular sensitivity via histaminergic and muscarinic pathways.[117,129]

PERIOPERATIVE AGENTS

Because of the number of different agents that are used before, during, and immediately after surgery, it is often difficult to determine which drug(s) are responsible for PONV. Opioids are frequently administered perioperatively and can be a cause of nausea and vomiting, as described above.

The mechanism by which inhaled anesthetic agents cause nausea and vomiting has not been elucidated. Like the opioid agonists, the inhaled anesthetics are thought to induce nausea and vomiting via stimulation of the CTZ, which in turn causes activation of the vomiting center.[121] Afferent sensory input from higher cortical centers may also contribute to PONV.[121,131,132] The vestibular nucleus is thought to play an important role in the nausea associated with anesthesia. Direct stimulation of serotoninergic receptors in the GI tract is also thought to contribute to PONV from the inhaled anesthetic agents.[133] After receiving and integrating the afferent input from the sources listed above, the vomiting center sends efferent signals to the respiratory and salivary centers and to the muscles directly involved in the act of emesis.[127]

Nitrous oxide is thought to produce nausea and vomiting via several separate mechanisms. It is believed that nitrous oxide stimulates the release of dopamine in the medulla.[131] In addition, nitrous oxide diffuses into the middle ear, resulting in pressure changes within the ear and stimulation of the vestibular apparatus.[154] Nitrous oxide can also produce abdominal distention during mask ventilation, leading to direct activation of the nociceptors and subsequent nausea and vomiting.[131,132] Finally, nitrous oxide exerts its analgesic effects via stimulation of opioid receptors in the central nervous system. This opioid-like activity is also thought to contribute to the emetogenic effects of nitrous oxide.[131]

During spinal anesthesia, the sympathetic nerves are essentially blocked, leading to an unopposed increase in vagal tone, which many think is a cause of PONV.[134] Others believe that the decrease in cerebral blood flow and subsequent hypoxia caused by reductions in blood pressure contribute to the nausea and vomiting associated with the administration of spinal anesthesia.[134]

The neuromuscular blocking agents produce nausea by blocking acetylcholine receptors found in muscle.[131] Although the mechanisms by which ketamine and many of the other perioperative agents induce nausea or vomiting or both are not well understood, one or more of the aforementioned mechanisms is likely involved.

CHEMOTHERAPY

Previously, direct stimulation of the CTZ was thought to be the main mechanism for chemotherapy-induced vomiting. Although CTZ stimulation is an important element, it is now known that the primary initial mechanism is direct damage to the GI mucosa and subsequent stimulation of GI neurotransmitter 5-HT$_3$ receptors. Once stimulated, the impulse is directed through the CTZ or directly to the emetic center. Other mechanisms involved include psychogenic stimulation through indirect or direct effects on the cerebral cortex, vestibular alterations, and taste and olfactory changes.[135] It is important to note that while 5-HT$_3$ receptor antagonists and NK-1 receptor antagonists (NK-1 RAs) can play an important role in the prevention of chemotherapy-induced emesis, there has been minor progress in the pharmacologic prevention of nausea.[135]

There are three distinct patterns of chemotherapy-related emesis: acute, delayed, and anticipatory. Acute emesis is mediated primarily by the release of serotonin within the first 8–12 hours after chemotherapy with drugs such as cisplatin.[136] With delayed vomiting, the primary mediator is substance P, which interacts preferentially with the NK-1 receptor.[136] It has been shown that substance P levels tend to trend upward 48 hours after the administration of cisplatin chemotherapy.[155] However, not all agents produce a significant release of substance P. Even cisplatin has a varying release of substance P at different doses. For example, cisplatin doses >75 mg/m^2 produced more substance P than cisplatin doses of <75 mg/m^2.[156] Delayed nausea and emesis can be quite debilitating for patients and may last for up to 1 week after chemotherapy. In addition to the role of substance P, there have been many other mechanisms describing the pathophysiology of delayed emesis. One theory holds that disruption of the blood–brain barrier occurs; this increases the risk of cerebral edema, which increases intracranial pressure. Other possible causes of delayed emesis include the interaction of serotonin with 5-HT$_4$ receptors and the development of hypomotility of the GI tract or gastroparesis.

Anticipatory nausea and emesis develop as a result of a classical conditioning (or Pavlovian) response to certain stimuli. Anticipatory effects do not occur unless a conditioned response develops as a result of previous adverse symptoms of chemotherapy.

MISCELLANEOUS AGENTS

The mechanisms responsible for nausea and vomiting associated with each of the miscellaneous agents listed in Table 40-1 vary, but typically involve one or more of the mechanisms described above. In addition, direct gastric or esophageal irritation, or both, is a mechanism of drug-induced nausea and vomiting that may occur with vitamins, minerals, and preparations used for electrolyte replacement.

Metronidazole may cause nausea and vomiting through several possible mechanisms. The development of an altered taste, often metallic, can lead to nausea.[141] When metronidazole is taken concurrently with ethanol, a disulfiram-like reaction consisting of flushing, nausea, vomiting, and tachycardia may occur.[141] It has been proposed that metronidazole, like disulfiram, inhibits hepatic aldehyde dehydrogenase, leading to an accumulation of acetaldehyde following the ingestion of ethanol.[142] However, in a double-blind, placebo-controlled study, 12 healthy male volunteers received 5 days of therapy with metronidazole or placebo plus ethanol 0.4 g/kg. Blood samples were taken every 20 minutes for 4 hours, and blood acetaldehyde and ethanol concentrations were measured. Volunteers were assessed for signs and symptoms of disulfiram-like reaction. Metronidazole did not affect blood acetaldehyde concentrations or lead to any objective or subjective adverse effects when used with ethanol in these subjects.[157]

An animal study also failed to find a correlation between the concomitant administration of metronidazole and ethanol and the development of high acetaldehyde concentrations.[143] An interesting observation, however, was that treated animals had an increase in brain serotonin concentrations after the use of metronidazole. The authors postulated that the mechanism of the metronidazole–alcohol interaction is a "toxic serotonin syndrome" and not an increase in acetaldehyde concentrations. Further study will be needed to elucidate the exact mechanism or mechanisms involved in the interaction between metronidazole and alcohol.

Erythromycin is notorious for its ability to induce nausea and vomiting, and several mechanisms are possibly involved. Erythromycin has been described as a motilin agonist that stimulates the contraction of the stomach and small intestines. It also is believed to induce the interdigestive migratory motor complex located in the stomach and proximal duodenum.[138] Disturbing this complex has been linked to vomiting, and effects have continued for up to 3 hours in a canine model.[139,140]

The mechanism of trimethoprim–sulfamethoxazole (TMP/SMX)-induced nausea and vomiting is unknown, although a disulfiram-like reaction (flushing, sweating, palpitations, drowsiness) has been described. Two patients receiving TMP/SMX double-strength were reported to have experienced a disulfiram-type reaction after the ingestion of 24–36 ounces of beer. One of the patients was rechallenged with TMP/SMX the next day after ingesting 6 ounces of beer, and a similar reaction developed. It is possible that TMP/SMX inhibits aldehyde dehydrogenase or the elimination of acetaldehyde via the cytochrome P-450 (CYP 450) hepatic pathway.[158]

Glucagon-like peptide (GLP-1) receptor agonists, such as exenatide and liraglutide, can induce nausea and vomiting by increasing glucose-dependent insulin secretion and decreasing glucagon secretion leading to delayed gastric emptying.[159]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Signs and symptoms associated with drug-induced nausea and vomiting are listed in Table 40-3. Conditions to consider in the differential diagnoses are presented in **Table 40-4**.[129,151,152,160,161]

OPIOIDS

Nausea and vomiting associated with opioid use normally occur immediately upon initiation of therapy and can last anywhere from a few days to a week or longer while the patient is taking the drug.[162-164] The majority of patients beginning opioid treatment experience a reduction or resolution of nausea and vomiting within the first week of therapy. A distinction should be made between nausea and vomiting caused by the opioid itself and that which occurs because of opioid-induced constipation. Patients usually develop a tolerance to the emetogenic effects of the opioid, but not to constipation.[116]

PERIOPERATIVE AGENTS

PONV associated with the use of the inhaled anesthetics most often occurs during the first 2 hours after surgery. Nausea and vomiting occurring 2–24 hours postoperatively have been associated with other factors, including opioid use, increased physical activity after surgery, and insufficient supplemental hydration.[165-167] Nausea and vomiting occurring at any time following surgery may be caused by any of several other factors unrelated to anesthesia, including decreased GI motility, anxiety, and uncontrolled pain.[168]

Table 40-4 Conditions to Consider in the Differential Diagnosis of Nausea and Vomiting

- Alcoholism
- Bacterial enterotoxins
- Bacterial or viral gastroenteritis

- Bulimia
- Cholecystitis
- Crohn disease
- Gastroparesis
- Hepatitis
- Increased intracranial pressure
- Irritable bowel syndrome
- Malignancy
- Mechanical obstruction
- Metabolic abnormalities
- Myocardial infarction
- Pancreatitis
- Peptic or gastric ulcer
- Postoperative nausea and vomiting
- Pregnancy
- Psychiatric disorders
- Radiation therapy
- Vestibular dysfunction

CHEMOTHERAPY

Chemotherapy-related emesis occurs with an acute, delayed, or anticipatory onset. **Table 40-5** describes the usual time of onset and duration of emesis associated with chemotherapy.[160] Delayed nausea and vomiting occurs more than 24 hours after the administration of chemotherapy although this phase may begin as early as 16 hours after cisplatin administration.[161] The development of anticipatory vomiting may occur in patients whose nausea and vomiting have not been well controlled during previous chemotherapy treatments. By the fourth treatment cycle, approximately 25% of patients have anticipatory nausea or vomiting or both.[125] In addition, more intense prior symptoms increase the likelihood that patients will have a conditioned or anticipatory response.[125] A patient who has severe chemotherapy-related nausea and emesis may remember the surroundings (including the healthcare providers present) during the event. The patient may subsequently associate the emesis with those surroundings or providers and may have anticipatory nausea or vomiting or both by just seeing or hearing the voice of those individuals.

Table 40-5 Onset and Duration of Emesis Associated with Antineoplastic Agents with >30% Emesis Frequency

Agent	Onset (hr)	Emesis Duration (hr)
Carboplatin	2–6	1 –48
Carmustine	2–6	4–24
Cisplatin	1–6	>24

Cyclophosphamide	6–12	6–36
Cytarabine ≥1,000 mg/m2	6–12	3–5
Dacarbazine	2–6	6–24
Dactinomycin	2–6	12–24
Daunorubicin	2–6	<24
Doxorubicin ≥20 mg/m2	2–6	6–24
Ifosfamide	3–6	6–12
Irinotecan	2–6	6–12
Lomustine	3–6	6–12
Mechlorethamine	0.5–2	6–24
Methotrexate ≥250 mg/m2	4–12	3–12
Streptozocin	2–6	12–24

MISCELLANEOUS AGENTS

Other drugs that cause clinical presentation and differential diagnosis of nausea and vomiting are similar to those described above. It should be noted, however, that it can be more difficult for healthcare providers to identify nausea and vomiting as being drug-induced when caused by agents infrequently associated with these effects. Under these circumstances, proper diagnosis can be delayed.

RISK FACTORS

OPIOIDS

Risk factors associated with the development of opioid-induced nausea and vomiting are listed in **Table 40-6**.[163] A retrospective study involving over 8,800 participants found that those 80 years of age or older were less likely to have opioid-induced nausea and vomiting than those between the ages of 16 and 45.[163] In addition, men were found to be less likely to experience opioid-induced nausea and vomiting than women. Race was also found to be a factor, with a higher risk of developing opioid-induced nausea and vomiting in whites than in blacks. The route of administration appears to affect the risk for developing nausea and vomiting in patients receiving parenteral opioids, with the intravenous (IV) route conferring a higher risk than the intramuscular (IM) or subcutaneous (sub-Q) routes. As would be expected, increasing the opioid dose increases the likelihood of nausea and vomiting.[163] Reasons for the majority of these risk factors are not known, but may be related to peak opioid concentrations.

Table 40-6 Risk Factors for Opioid-Induced Nausea and Vomiting

- Concomitant administration of other potentially emetogenic agents
- Dose (higher dose is greater than lower dose)
- Opioid exposure (patient with no previous opioid exposure is greater than patient with previous opioid exposure)
- Oral doses taken without food
- Race (whites greater than blacks)
- Route of administration (intravenous > intramuscular and subcutaneous)
- Sex (females greater than males)
- Younger age (patients 16–45 yr of age are at higher risk than those ≥80 yr)

PERIOPERATIVE AGENTS

The various risk factors associated with an increased incidence of drug-induced PONV are listed in **Table 40-7**.[122,123,165-167] No single factor is of primary importance in accurately predicting which patients will experience PONV, although female sex has shown to be the most predictive. This can be appreciated by reviewing the simple models available to aid clinicians in predicting the PONV risk in adults and children (**Table 40-8**).[122,123] The primary PONV risk factors have been shown to include female sex, nonsmoking status, previous history of PONV or motion sickness, childhood to young adulthood ages, long duration of surgery, and the use of volatile anesthetics, nitrous oxide, or perioperative opioids. The specific type of surgical procedure also affects the risk of PONV, with gynecological and abdominal surgeries conferring a higher risk of PONV.[169]

Table 40-7 Risk Factors for Postoperative Nausea and Vomiting

Anesthesia related

- Experience level of anesthesiologist
  - Less experienced is greater than more experienced
- Type of anesthesia
  - General is greater than spinal is greater than peripheral block
- Use of nitrous oxide

Other factors

- Eating or drinking too soon after surgery
- Increased postoperative movement
- Perioperative administration of opioids
- Presence of postoperative pain

Patient related

- Age
  - Children (6–16 yr) greater than adults greater than infants (<12 mo)

- Female sex
- Nonsmoker
- Presence of delayed gastric emptying
  - Obstruction
  - Pregnancy
  - Diabetes
- Prior history of PONV or motion sickness

Surgery related

- Decrease in systolic blood pressure by ≥35% during surgery or induction of anesthesia
- Increased duration of surgery
  - Each 30-minute surgery increment increases PONV risk by 60%
- Type of surgery
  - Laparoscopy, laparotomy, breast, strabismus, plastic surgery, maxillofacial, gynecologic, abdominal, neurologic, ophthalmologic, urologic

PONV = postoperative nausea and vomiting.

Table 40-8 Assessing Risk for Postoperative Nausea and Vomiting

ADULT PONV RISK SCORE PREDICTORS

One point for each risk factor: female sex, nonsmoker, history of PONV, postoperative opioids

No. of Points	Approximate Risk of PONV (%)
0	10
1	20
2	40
3	60
4	80

CHILDREN PONV RISK SCORE PREDICTORS

One point for each risk factor: surgery lasting ≥30 minutes, age ≥3 years, strabismus surgery, personal or family history of PONV

No. of Points	Approximate Risk of PONV (%)
0	10
1	10
2	30
3	55
4	70

PONV = postoperative nausea and vomiting.

Patients who are ultrarapid metabolizers of *CYP2D6*, which codes for a CYP isozyme important in drug metabolism, may be less likely to respond as expected to agents used to control PONV. All 5-HT_3 receptor antagonists except granisetron are substrates for *CYP2D6* and may be susceptible to increased metabolism and clearance in patients who are *CYP2D6* ultrarapid metabolizers. This relationship was studied in 250 patients receiving ondansetron 4 mg IV for PONV prevention.[168] The incidence of vomiting in poor, intermediate, extensive, and ultrarapid metabolizers was found to be 1 in 12 (8%), 5 in 30 (17%), 26 in 176 (15%), and 5 in 11 (45%), respectively. There was no difference in the incidence of nausea between groups.

Another study compared granisetron 1 mg intravenously and dolasetron 12.5 mg IV in a prospective, randomized, double-blind study of 150 adult patients.[170] Because *CYP2D6* does not metabolize granisetron, it was theorized it would be more effective than dolasetron in rapid metabolizers. Overall, a complete response (no vomiting or rescue medication required) occurred more frequently in the granisetron group (54.7%) as compared with the dolasetron group (38.7%). Ultrarapid metabolizers who received dolasetron (n = 6) experienced more vomiting episodes than those (n = 4) who received granisetron (six episodes versus one episode, respectively).

Table 40-9 Risk Factors for Chemotherapy- Induced Nausea and Vomiting

Chemotherapy-specific factors

- Administration of multiple agents on the same day
- Circadian cycle with cisplatin (morning administration is greater than evening)
- Emetogenicity of agent
- High dose
- Infusion rate (bolus is greater than continuous infusion)
- Lack of maintenance antiemetics after chemotherapy

History

- Emesis from chemotherapy
- Hyperemesis with pregnancy
- Motion sickness

Patient-specific factors

- Age (<50 yr)
- Anxiety
- Enhanced cytochrome P450 2D6 activity
    - Ultrarapid metabolizers of 5-HT_3 receptor antagonists (except granisetron)
- Feeling hot or warm after chemotherapy
- Female sex
- History of minimal long-term alcohol consumption
- Poor performance status

Risk factors for delayed nausea and emesis

- Female sex
- Poor control in the acute phase (0–24 hr after chemotherapy)
- Poor control with first cycle

- Use of certain chemotherapy agents
    - Anthracyclines
    - Carboplatin
    - Cisplatin, especially with dose >90 mg/m^2
    - Cyclophosphamide

CHEMOTHERAPY

The most common risk factors for CINV are listed in **Table 40-9**.[125,135,160,171-173] As with PONV, CYP metabolizer status is an area of interest as it relates to the effectiveness of antiemetics in preventing CINV. All 5-HT_3 receptor antagonists except granisetron are substrates for *CYP2D6*. In a study to investigate the efficacy of ondansetron and tropisetron based on *CYP2D6* genotype, patients who were ultrarapid metabolizers had greater intensity of vomiting and nausea as well as lower antiemetic serum concentrations as compared with poor metabolizers.[173] It was determined that approximately 50 subjects would have to be genotyped to protect one patient from severe emesis. The feasibility of identifying patients' *CYP2D6* genotype and thereby assisting health professionals in adjusting antiemetic regimens is unclear.

MISCELLANEOUS AGENTS

General risk factors for nausea and vomiting associated with other agents include a recent increase in medication dose, a change in the patient's underlying renal or hepatic function resulting in a higher drug concentration, and drug–food, drug–drug, and drug–disease interactions. Patients with a history of multiple drug allergies or side effects typically have a higher incidence of nausea and vomiting when exposed to new drugs.

MORBIDITY AND MORTALITY

OPIOIDS

Nausea and vomiting associated with any drug can lead to a decreased adherence to prescribed therapy. With opioid-induced nausea and vomiting, decreased adherence can lead to uncontrolled pain and severely compromise the patient's quality of life. Nausea and vomiting may also prevent patients from eating, resulting in nutritional deficiencies that can exacerbate other underlying medical conditions. In severe cases of drug-induced emesis, dehydration with subsequent electrolyte disturbances can occur, leading to potentially life-threatening complications.

PERIOPERATIVE AGENTS

PONV causes significant morbidity. Even minor episodes of nausea and vomiting can lead to delays in eating, drinking, and walking postoperatively thus retarding recovery. In addition, nausea and vomiting may prevent patients from taking oral medications. If vomiting is severe, dehydration and electrolyte disturbances such as hyponatremia and hypokalemia can occur. Forceful retching can cause Mallory-Weiss tears in the esophagus as well as abdominal wound dehiscence.[174] In addition, the risk for aspiration of GI contents is increased with protracted postoperative emesis. PONV may delay the patient's transfer from the postanesthesia care unit, which could result in an increased length of hospital stay.[174,175] Patients who undergo outpatient surgery and experience significant PONV may have to be admitted to the hospital.

CHEMOTHERAPY

The incidence of mortality related to CINV is unknown. However, the incidence of morbidity related to CINV has been evaluated. In a longitudinal secondary analysis performed on data from a prospective, observational quality-of-life study involving 200 newly diagnosed cancer patients who underwent chemotherapy, 62% of patients experienced nausea and 27% experienced vomiting; furthermore, patients with nausea experienced significant quality-of-life impairment and psychological distress compared to those unaffected in the areas of physical, role and social functioning, fatigue, appetite loss, overall physical health, and overall quality of life.[176] Similarly, patients with vomiting experienced significant quality-of-life impairment and psychological stress compared to those unaffected in the areas of physical, role and social functioning, fatigue, appetite loss, sleep disturbance, overall physical health, and cancer distress.[176] The sequelae can be quite dramatic and may lead to dissatisfaction with the healthcare system and nonadherence to the treatment plan. In a trial comparing metoclopramide and placebo in patients receiving high-dose cisplatin, placebo-treated patients experienced an average of 10.5 emetic episodes in a 24-hour period and had nausea and vomiting lasting over 3.6 hours.[51] This type of unrelenting nausea and vomiting can lead to metabolic imbalances, diminished quality of life and functional ability, nutritional deficiencies, anorexia, decreased performance and psychological status, wound dehiscence, and esophageal tears and can ultimately lead to withdrawal from cancer treatment programs.[161,177]

In a retrospective study to ascertain the impact of therapy-related nausea and vomiting on the outcomes of patients receiving cisplatin for lung, ovarian, and testicular cancer, an association was found between the incidence of vomiting and the length of hospital stay per cycle of chemotherapy.[178] Patients with lung cancer who did not have emesis had an average hospitalization of 2.1 days, versus 4.2

days if they experienced emesis. Patients with testicular cancer receiving a 3-day chemotherapy regimen had an average of 5.5 versus 4.2 days of hospitalization if they experienced emesis versus no emesis. In the lung cancer group, 2.5% of patients stopped therapy for reasons related to poorly controlled emesis; however, survival was not affected by this choice. No patient in the ovarian or testicular cancer groups withdrew from the study because of vomiting. Even though most patients received prophylactic 5-HT_3 receptor antagonists, the development of nausea and vomiting was still found to prolong hospitalization.

MISCELLANEOUS AGENTS

Tigecycline, an antibiotic related to minocycline, can induce nausea and vomiting. In a large randomized study, 1% of patients treated with tigecycline stopped taking the drug because of nausea and vomiting versus none in the vancomycin and aztreonam groups.[96] In another study, 2.5% of the patients treated with tigecycline discontinued therapy early because of nausea or vomiting or both.[95]

Up to 24% of patients receiving fluoxetine for depression may experience treatment-related nausea.[103,104] Fortunately, only 8% or fewer discontinue therapy as a result.[103,104]

Adherence problems caused by drug-induced nausea and vomiting can affect the morbidity and mortality of patients with human immunodeficiency virus infection who take complicated regimens such as highly active antiretroviral therapy (HAART). A study evaluated the self-reported adverse effects of patients taking HAART for at least 1 month and whether or not these adverse effects had an impact on adherence.[179] A total of 358 patients were evaluated. Nonadherence in the past 3 days was reported by 22% of patients and 25% reported not refilling their medications in a timely fashion. Those with nausea had a 4.47 times greater risk of poor adherence. However, it is unknown if nonadherence affected their overall morbidity or mortality.

Erythromycin has a significant GI adverse effect profile. In a randomized controlled trial, therapy with IV erythromycin had to be discontinued in 10% of patients because of severe GI toxicity.[93]

It is well known that oral iron preparations can cause a variety of GI symptoms. In a study evaluating the relationship of nausea and vomiting to adherence with iron therapy in higher and lower socioeconomic groups, it was found that adherence decreased from 82% to 48% in members of the lower socioeconomic group in whom nausea and vomiting developed.[107] In the higher socioeconomic group, however, adherence rates remained similar in patients with or without nausea and vomiting.

PREVENTION

General guidelines to help prevent drug-induced nausea and vomiting are listed in **Table 40-10**.

OPIOIDS

Nausea and vomiting following the initiation of opioid therapy is relatively common and should be anticipated. Patients should be informed of the potential for this effect before the initiation of therapy. In addition, appropriate antiemetic therapy should be available in case nausea or vomiting occurs. Any conditions or medications that could exacerbate the adverse GI effects of opioid analgesics should be identified and steps taken to remove them if possible.

Starting at a lower dose and titrating upward may help minimize some of the emetogenic effects of opioid therapy. When patients require continuing therapy with opioids, a bowel regimen containing a stimulant laxative should be initiated to help prevent the constipation that is common with this class of drugs. Oral opioid analgesics may be taken with meals to help decrease local gastric emetogenic effects. A study evaluating the effect of food on an oral, extended-release formulation of hydrocodone in healthy volunteers showed that food did not affect plasma concentration over time; however, 50% of volunteers experienced nausea in the fasting state while only 25% experienced nausea in the fed state.[180] In hospitalized patients, switching from oral to parenteral administration may be useful; local effects on the GI tract may be decreased, although the central emetogenic effects of the opioid will remain. In patients who experience significant nausea or vomiting, a switch to a different opioid analgesic may be helpful. There is no clinical evidence supporting the use of prophylactic antiemetic agents in all patients beginning opioid therapy.[162,181,182]

Table 40-10 Approaches to Help Prevent Drug-Induced Nausea and Vomiting

- If possible, avoid agents with high emetogenic potential
- For opioid-induced nausea and vomiting:
  - Use lowest effective dose
  - Take oral opioids with food to minimize nausea and vomiting

For PONV

- Ensure that patient is fully hydrated and that pain is controlled before surgery
- Avoid inhaled anesthetics
- For the patient at risk for PONV, administer antiemetic perioperatively
- Minimize motion and activity after surgery
- Minimize eating and drinking up to 8 hr after surgery

For chemotherapy-induced nausea and vomiting

- Assess risk factors and adjust antiemetics as necessary
- Patients need to be protected throughout full period of risk with highly emetogenic agents (at least 3 days) and moderately emetogenic agents (at least 2 days)
- For highly and moderately emetogenic agents, use a 5-HT_3–receptor antagonist and dexamethasone
- For those at risk for delayed nausea and vomiting, use a NK-1 antagonist or olanzapine in combination with a 5-HT_3 receptor antagonist and dexamethasone
- For low emetogenic agents, use dexamethasone, metoclopramide, prochlorperazine, or a 5-HT_3–receptor antagonist
- For minimally emetogenic agents, no routine prophylaxis recommended
- Follow established, peer-reviewed guidelines for the prevention of postoperative and chemotherapy-induced nausea and vomiting
- Identify high-risk individuals and use prophylactic antiemetics according to guidelines
- Adjust antiemetics as necessary for patients in whom previous antiemetic regimens have failed
- Eating small, frequent meals, choosing healthful foods, controlling amount of food consumed, and eating food at room temperature may help alleviate nausea/vomiting.

PONV = postoperative nausea and vomiting.

PERIOPERATIVE AGENTS

The incidence of PONV has decreased dramatically since the development of newer inhaled anesthetics, the increasing use of IV anesthesia, and the advent of ultra-short-acting neuromuscular blocking agents.[131,132] Before any surgical procedure, a thorough preoperative history and physical examination should be conducted.[174] Patient-specific risk factors for PONV should be identified, along with risk factors associated with the type of surgery and the type and duration of anesthesia planned. A comprehensive preoperative evaluation is the most important step in reducing the likelihood of intraoperative and postoperative complications.[183]

Several steps can help reduce a patient's risk for PONV. Rather than using anesthetic agents known to cause nausea and vomiting, those with less emetogenic potential can be used. Propofol has been found to cause significantly less nausea and vomiting when used during induction and during maintenance of anesthesia as compared with many of the more traditional inhaled or IV agents.[184-189] Nitrous oxide causes nausea and vomiting in a significant number of patients.[183,185] In patients at high risk for PONV or those in whom postoperative vomiting may hinder recovery, the risks of using nitrous oxide may outweigh any potential benefit. Perioperative opioid use should be minimized in patients at high risk for PONV. However, because uncontrolled postoperative pain can itself lead to PONV, adjustment of the opioid dose should be done cautiously.

Patients should be instructed not to eat or drink anything immediately before their surgery. In addition, discouraging eating and drinking within the first 8 hours postoperatively can decrease the risk of PONV. Patients should not be moved unnecessarily in the immediate hours following surgery, as sudden movements and positional changes can precipitate nausea.[120] Techniques that have been shown beneficial in reducing the incidence of PONV include the administration of supplemental IV fluids preoperatively, maintenance of blood pressure and increased oxygenation intraoperatively, and frequent nasogastric suctioning postoperatively.[121,132,165]

Patients at high risk for PONV (e.g., those who have experienced nausea, vomiting, or both after previous surgical procedures) and those in whom PONV is likely to significantly delay or complicate recovery (e.g., patients undergoing open abdominal surgery) may benefit from prophylactic antiemetic therapy.[174,190,191] Prophylactic antiemetic administration in patients with no history of PONV or in those with no identifiable risk factors is not warranted. In these patients, the PONV risk is estimated to be only 10%.[119]

Several antiemetic agents have been shown to be particularly effective in PONV prevention, including promethazine, droperidol, granisetron, dolasetron, ondansetron, palonosetron, dexamethasone, scopolamine, and aprepitant.[175,189,192-194] The usual dose of promethazine for the PONV prevention is 25 mg administered orally (PO), rectally (PR), IM, or IV. However, a retrospective analysis showed no difference in complete response (no PONV and no further rescue) between 6.25 mg of promethazine and higher doses.[195] Promethazine frequently causes drowsiness, especially when given with opioid analgesics or other sedating agents. In addition, promethazine can occasionally cause extrapyramidal symptoms.[189] In 2004, the U.S. Food and Drug Administration (FDA) required the addition of a black box warning to the labeling for promethazine that included a contraindication for use in children <2 years of age and a cautionary warning regarding use in children >2 years of age.[196]

Droperidol should be administered in doses of 0.625–1.25 mg IM or slow IV push for PONV prevention. The use of droperidol has been associated with prolongation of the QT interval and ventricular tachycardia, including torsades de pointes. Droperidol is contraindicated in patients with QT interval prolongation and should be used with caution in patients at risk for cardiac arrhythmias. Like promethazine, droperidol can cause extrapyramidal symptoms.[121]

Ondansetron, a 5-HT_3 receptor antagonist, has been shown to be effective for PONV prevention and treatment in doses of 4 mg IV or 8 mg PO.[197-203] A single 4-mg IV dose has been shown to be effective in preventing and treating postoperative emesis for up to 24 hours.[204-206] It should be noted that ondansetron and the other 5-HT_3 receptor antagonists are more effective in preventing vomiting than they are in preventing nausea.[192] A 4-mg IV dose has a number needed to treat (NNT) of 6 for prevention of vomiting and a NNT of 7 for prevention of nausea.[192] Ondansetron is associated with relatively few adverse effects as compared to many of the other antiemetics, although some studies have shown QT interval prolongation in patients receiving this agent.[189]

Palonosetron has also been used successfully in PONV prevention. Over 500 patients were randomly assigned to receive palonosetron 0.025 mg, 0.05 mg, or 0.075 mg or placebo IV prior to anesthesia.[207] The incidence of complete response (no vomiting and no rescue antiemetics required) was evaluated during the period after surgery (0 to 72 hours). Of 138 patients treated with 0.075 mg palonosetron and evaluated for 24 hours after surgery, 43% had a complete response versus 26% in the placebo group. For 24–72 hours after surgery, there was no significant difference between palonosetron and placebo with respect to reducing PONV. Over the 72-hour period, the nausea intensity improved with palonosetron but was not statistically different as compared with placebo. The other 5-HT_3 receptor antagonists, dolasetron and granisetron, had similar efficacy in PONV prevention.

Dexamethasone has been used for the prevention of chemotherapy-induced emesis for many years, and it is now used for PONV prevention. The mechanism of action of corticosteroids, including dexamethasone, for the prevention of nausea and vomiting is not clearly understood but may involve the inhibition of prostaglandin and cytokine release.[141,208] Dexamethasone interacts with glucocorticoid receptors found in different areas of the brain such as the nucleus tractus solitarius and the area postrema, which may contribute to its antiemetic effects. Dexamethasone doses of 8 mg IV or 10 mg PO have been shown to be effective in reducing the incidence of nausea and vomiting to 8–20% versus 36–40% compared with placebo after surgery.[208] Dexamethasone should be administered before the induction of anesthesia for maximal benefit. Dexamethasone, like other corticosteroids, has many adverse effects; however, administration of single doses minimizes this possibility.[192,208]

A multicenter, randomized, placebo-controlled study of over 5,100 patients found similar rates of efficacy in decreasing the incidence of PONV with prophylactic administration of droperidol (1.25 mg IV), dexamethasone (4 mg IV), or ondansetron (4 mg IV).[200] Overall, 54.5% of the patients in this study had a history of PONV or motion sickness, known risk factors for PONV. Over 78% of the patients received opioids postoperatively, further increasing the PONV risk. Thirty-four percent of the patients had at least one episode of postoperative nausea or vomiting or both. As expected, patients who had received inhaled anesthetics, nitrous oxide, or both had a higher incidence of PONV as compared with those who received propofol anesthesia. Patients who received propofol had a 19% lower incidence of PONV as compared with those who received inhaled anesthetics. Those who received oxygen and nitrous oxide had a 12% higher incidence of PONV as compared with those who received oxygen and nitrogen. Without prophylactic antiemetics, 52% experienced PONV, as compared with 37%, 28%, and 22% when one, two, and three antiemetic agents, respectively, were given. The authors suggest that single-agent prophylaxis with dexamethasone, droperidol, or ondansetron is equally effective. In patients at high risk for PONV or in those in whom postoperative vomiting may be detrimental, a combination prophylactic antiemetic regimen may be warranted.[200]

The NK-1 RA aprepitant is one of the most recent agents to demonstrate efficacy for PONV prevention. A large study compared aprepitant to ondansetron for PONV prevention.[194] Over 800 patients were randomly assigned to receive either a single dose of aprepitant 40 mg PO, aprepitant 125 mg PO, or ondansetron 4 mg IV preoperatively. The primary outcome was the incidence of complete response (no vomiting and no rescue antiemetics required) in the 24 hours after surgery. There were no significant differences among the three groups, with complete response reported in 45%, 43%, and 42% of patients, respectively. However, when evaluating vomiting only, 90% and 95% of patients in the aprepitant groups had not vomited in the 24 hours after surgery as compared with 74% in the ondansetron group. This beneficial effect carried over for 48 hours after surgery. In terms of need for rescue antiemetics and nausea control, there were no differences among the groups. As with other aprepitant trials, greater benefit was demonstrated in the prevention of vomiting than in the control of nausea.

Two other frequently used antiemetic agents, metoclopramide and prochlorperazine, have been shown to be of benefit for prophylaxis in PONV in some clinical trials but no more effective than placebo at preventing PONV in others.[209-212] Drugs and doses for the prophylaxis of PONV in adults are listed in **Table 40-11**.[141,160,192] Appropriate dose adjustments are required for pediatric use.[160]

Recent data suggest that gabapentin may decrease PONV. A single oral dose of 600 mg given 1 to 2 hours preoperatively in addition to a standard multimodal antiemetic regimen has shown to result in a significant reduction in the incidence of nausea and vomiting, thereby decreasing the need for rescue antiemetics in the postoperative setting when compared to the standard regimen alone.[213] The majority of the clinical trials conducted utilizing gabapentin as an adjunct in various preoperative regimens focused on its efficacy in reducing postoperative pain. The drug's activity in reducing PONV was discovered serendipitously.[213,214] There are a very small number of trials that focus on gabapentin's reduction in the incidence of PONV as a primary endpoint; the ones which exist also suggest that a single dose of the drug, when given in combination with the standard preoperative antiemetic agents, results in a reduction in PONV incidence.[214,215] It should be noted that in most of these trials, the patients studied received general anesthesia.[215]

The exact mechanism by which gabapentin exerts its antiemetic effect is not known. One proposed mechanism involves gabapentin causing a decrease in calcium signaling in the area postrema. Another possible mechanism involves a decrease in tachykinin neurotransmission, while yet another implicates postoperative anti-inflammatory effects.[216,217] A more simple explanation involves the drug's established activity in reducing postoperative pain, which may lead to a reduction in perioperative opioid requirements and their associated nausea and vomiting.[218] It is likely that a combination of these as well as other, yet undiscovered, mechanisms leads to gabapentin's reduction in PONV.[216-218]

Table 40-11 Pharmacotherapy to Help Prevent Drug-Induced Postoperative Nausea and Vomiting

Drugs	Dose	Timing with Respect to Anesthesia/Surgery
Aprepitant	40 mg PO	At induction
Dexamethasone	4–8 mg IV	At induction
Dimenhydrinate	1 mg/kg (maximum, 100 mg) IV	Before induction
Dolasetron	12.5 mg IV	At end of surgery
Droperidol	0.625–1.25 mg IV	At end of surgery
Ephedrine	0.5 mg/kg IM	At end of surgery
Granisetron	0.35–1.5 mg IV	At end of surgery
Haloperidol	0.5–2 mg IV/ IM	At end of surgery
Methylprednisolone	40 mg IV	At induction
Ondansetron	4 mg IV	At end of surgery
Palonosetron	0.075 mg IV	Before induction
Prochlorperazine	5–10 mg IV/ IM	At end of surgery
Promethazine	6.25–25 mg IV	At induction
Scopolamine	Transdermal patch	Evening before or 2 hr before induction
Tropisetron	2 mg IV	At end of surgery

IM = intramuscular, IV = intravenous, PO = oral.

Ginger (*Zingiber officinale*) has been used as a medicinal agent for nearly 2,500 years. The mechanism of a reported antiemetic effect with ginger is unknown but studies suggest that phytochemicals contained in the root may function as a 5-HT_3 antagonist and a NK-1 RA.[219] Evidence for the use of ginger for the prevention of PONV has been equivocal. A meta-analysis of six randomized placebo-controlled trials that included 538 patients comparing doses of ginger ranging from 100 mg to 1 g found no difference in the pooled relative risk in preventing PONV 24 hours after surgery (RR 0.84, 95% CI 0.69–1.03).[220] However, a subsequent meta-analysis comparing five randomized placebo-controlled trials that included 363 patients and a fixed dose of 1 g of ginger found a difference in the pooled relative risk favoring ginger in preventing PONV 24 hours after surgery (RR 0.65, 95% CI 0.51–0.84).[221] Ginger may play a role in PONV, but further studies need to be conducted elucidating which phytochemical in ginger is responsible for this effect.

CHEMOTHERAPY

Prevention of CINV is an important goal, and several national and international oncology groups have published recommendations to assist with this objective.[161,222-224] **Table 40-12** provides detailed information regarding pharmacotherapy for the prevention of acute and delayed CINV.[161,222,223] Although there has been good success in preventing emesis in the majority of patients, a similar reduction in the incidence of nausea has not been achieved.

Most protocols for the prevention CINV include a 5-HT_3 receptor antagonist and dexamethasone. The 5-HT_3 receptor antagonists have all been considered clinically equivalent for the prevention of acute nausea and vomiting; however, palonosetron is the preferred 5-HT_3 receptor antagonist for preventing acute nausea and vomiting if/when a NK-1 RA is not to be used in combination.[161,222] For the prevention of acute emesis in patients receiving highly emetogenic chemotherapy, the use of a corticosteroid such as dexamethasone in combination with a 5-HT_3 receptor blocker and NK-1 RAs should be considered unless contraindicated. For patients receiving cisplatin chemotherapy, the dose of dexamethasone should be at least 12 mg but preferably 20 mg/day, based on findings of the Italian Group for Antiemetic Research.[225] This group also evaluated dexamethasone use in patients receiving anthracyclines, carboplatin, or cyclophosphamide.[226] Their results demonstrated that lower doses of dexamethasone (a single 8-mg IV dose) were as effective as higher doses (24 mg) for the prevention of acute emesis in this patient population.

Table 40-12 Approaches to Prevent Chemotherapy-Induced Nausea and Vomiting

- Ascertain acute and delayed nausea and vomiting risk factors and adjust antiemetics as necessary
- Multiple-day chemotherapy regimens may require additional days of antiemetic prophylaxis
- 5-HT_3–receptor antagonists are typically given as a single dose before the emetogenic agent
- To improve antiemetic response, corticosteroids should be administered with the 5-HT_3–receptor antagonist
- Lorazepam or another benzodiazepine may be administered to reduce anxiety during the chemotherapy regimens
- H2 blockers or proton pump inhibitors may be added to prevent dyspepsia
- For patients receiving a highly emetogenic agent:
    - o On day 1, 5-HT_3–receptor antagonist[a], NK-1 antagonist[b], and steroid[c]
    - o On days 2–3, if aprepitant given, aprepitant 80 mg PO and dexamethasone 8 mg PO/IV days 2–4; otherwise, dexamethasone 8 mg PO/IV on day 2 then 8 mg PO/IV BID days 2–4; if fosaprepitant given

day 1 or dexamethasone, 8 mg PO/IV BID days 2–4 if rolapitant given

- For patients receiving a moderately emetogenic agent:
  - On day 1, 5-HT_3–receptor antagonist[a] and dexamethasone 12 mg PO/IV plus aprepitant[d] 125 mg PO or fosaprepitant 150 mg IV, or rolapitant 180 mg PO in select patients at high risk of delayed nausea and vomiting
  - On days 2–3, if aprepitant given, aprepitant 80 mg PO daily with or without dexamethasone 8 mg PO daily; if fosaprepitant or rolapitant, with or without dexamethasone, 8 mg PO/IV daily
- For patients at lower risk of delayed emesis, administer a 5-HT_3–receptor antagonist plus dexamethasone on day 1 with or without dexamethasone on days 2–3
- For patients receiving low emetogenic agent:
  - Dexamethasone 12 mg PO/IV, prochlorperazine 10 mg PO/IV, and then q 6 hr PRN, metoclopramide 10–40 mg PO/IV then either q 4–6 hr PRN, or serotonin 5-HT_3–receptor antagonist[e]
- For patients receiving a minimal-risk agent:
  - No routine prophylaxis

IV = intravenous, PO = oral; PRN = as needed.

[a] Palonosetron 0.25 mg IV (preferred only when not combined with a NK-1 RA); ondansetron 8–16 mg IV or 16–24 mg PO; granisetron 0.01 mg/kg (1 mg max) IV or 2 mg PO or transdermal patch (3.1 mg/24 hr) applied 24–48 hr before first dose of chemotherapy; dolasteron 100 mg PO.

[b] Aprepitant 125 mg PO; fosaprepitant 150 mg IV; rolapitant 180 mg PO.

[c] Dexamethasone 12 mg PO/IV if aprepitant or fosaprepitant given; dexamethasone 20 mg PO/IV if rolapitant given.

[d] Data from large randomized trials with aprepitant support use in patients receiving cisplatin (70 mg/m2) or anthracycline–cyclophosphamide combination regimens for breast cancer.

[e] Dolasteron 100 mg PO; granisetron 1–2 mg PO; ondansetron 8–16 mg PO.

Palonosetron, a 5-HT_3 receptor antagonist with a longer half-life (approximately 40 hours) and higher 5-HT_3–receptor binding as compared with other 5-HT_3 receptor antagonists, is used for the prevention of acute and delayed nausea and vomiting from highly and moderately emetogenic chemotherapy.[207] A study evaluating single-dose palonosetron versus ondansetron (both without dexamethasone) demonstrated efficacy (no emesis and no rescue medication required) of palonosetron as compared with ondansetron during the first day (81% versus 69%), days 2 to 5 (74% versus 55%), and over the entire period of 1 to 5 days (69% versus 50%) of chemotherapy.[227] The proportion of nausea-free patients was similar between the groups on days 1 to 2, while palonosetron-treated patients had significantly less nausea on days 3 to 5.

Aprepitant and the IV formulation fosaprepitant are NK-1 RAs and are important agents in the prevention of acute and delayed nausea and vomiting from highly (e.g., cisplatin) and moderately (e.g., anthracycline-cyclophosphamide combinations) emetogenic chemotherapy.[228] A study evaluating an aprepitant regimen versus standard therapy in the prevention of CINV in patients receiving cisplatin showed that a regimen including aprepitant, ondansetron, and dexamethasone was more effective than a regimen of ondansetron and dexamethasone.[229] In days 1 to 5 after cisplatin, 73% of aprepitant recipients versus 52% of patients in the control group had a complete response (no emesis and no rescue medications required). In terms of nausea control, there were no significant differences between the groups during the acute and delayed phases or overall.

In another study, patients receiving anthracycline–cyclophosphamide regimens were randomly assigned to receive oral ondansetron and dexamethasone with or without aprepitant on day 1.[230] On days 2 to 3, patients received either aprepitant or placebo with no additional dexamethasone. Overall, patients who received aprepitant had a better complete response (no emesis and no rescue medications required) than the placebo group (51% versus 42%). When the effects were evaluated in each phase separately, patients taking aprepitant achieved a better complete response during the acute phase (76% versus 69%); however, there was no significant difference in the delayed phase. Also, as in other trials, there was little or no impact on nausea in either group.

In an attempt to define the smallest aprepitant dose needed to effectively prevent CINV, a study was completed evaluating a single 125-mg dose of aprepitant. This randomized, double-blind, placebo-controlled trial evaluated palonosetron 0.25 mg IV, aprepitant 125 mg PO, and dexamethasone PO versus the standard 3-day aprepitant (125 mg on day 1 and 80 mg on days 2 and 3) regimen.[231] Overall, during days 1 to 5 both groups displayed similar effectiveness in the prevention of emesis (93%) and similar outcomes in the control of nausea and complete response (no emesis and no rescue antiemetics required). Further studies will be necessary to verify these findings. The idea of a single oral aprepitant dose is solidified with the FDA approval of a single IV dose of fosaprepitant.[232]

Netupitant–palonosetron (NEPA) is the first antiemetic combination agent for CINV. In three pivotal clinical trials, NEPA plus dexamethasone demonstrated improvement over oral palonosetron plus dexamethasone for acute and delayed nausea and vomiting for cisplatin-based highly emetogenic chemotherapy (overall: 89.6% versus 76.5%, respectively) or anthracycline–cyclophosphamide chemotherapy (overall: 74.3% versus 66.6%, respectively).[233] NEPA plus dexamethasone also showed significant improvement in nausea in both the delayed and acute settings over oral palonosetron plus dexamethasone for cisplatin-based highly emetogenic chemotherapy (overall: 89.6% versus 79.4%, respectively) or anthracycline-cyclophosphamide-based chemotherapy (overall: 74.6% versus 69.1%, respectively).[233]

Rolapitant is a highly selective oral NK-1 RA utilized in the prevention of acute and delayed nausea and vomiting from highly and moderately emetogenic chemotherapy. Three studies have shown, after cycle 1, that rolapitant combined with granisetron and dexamethasone was significantly more effective than granisetron and dexamethasone during the delayed phase of CINV (70.1–72.7% versus 58.4–61.9%, respectively).[233]

Olanzapine has been evaluated as first-line prophylaxis of CINV. An olanzapine/5-HT_3 receptor antagonist/dexamethasone combination regimen showed superior delayed and overall complete response rates compared to 5-HT_3 receptor antagonist/dexamethasone combination regimen in a phase III trial.[233] Another phase III trial compared olanzapine and aprepitant, both in combination with dexamethasone and palonosetron.[234] Complete response rates were comparable for the olanzapine and aprepitant regimens (97% acute, 77% delayed, 77% overall phases versus 87% acute, 73% delayed, 73% overall phases, respectively). Furthermore, patients without nausea in the olanzapine group were 87% acute, 69% delayed, and 69% overall compared to 87% acute, 38% delayed, and 38% overall for the aprepitant group.[234]

In patients who experience breakthrough nausea and emesis, changes should be made to the prophylactic regimen prior to the next chemotherapy session. When an antiemetic regimen fails, replacing the 5-HT_3 receptor blocker with another appears to benefit approximately 50% of patients.[235-237] If patients are experiencing delayed vomiting, adding NK-1 RAs or changing the 5-HT_3 receptor blocker to palonosetron or both are appropriate choices. The addition of a benzodiazepine may assist patients with anxiety problems. For those patients experiencing nausea, the use of olanzapine with a 5-HT_3 receptor blocker and dexamethsone has been shown to help prevent nausea.[161]

Despite the existence of published guidelines, it should be noted that patients have unique nausea and emesis risk factors and may respond differently to both chemotherapy agents and antiemetics. Therefore, individualization of the antiemetic regimens is necessary to provide optimal emetic control.

MISCELLANEOUS AGENTS

Drugs known to induce nausea and vomiting should be avoided if there are equally effective alternative agents available. Unfortunately, it is difficult to predict which patients will experience nausea or vomiting because these adverse events occur sporadically. Taking an oral medication with food may decrease nausea and vomiting in some cases and with some agents; however, drug–food interactions should be considered and avoided. Prophylactic use of an antiemetic may be necessary and appropriate in some situations. Ginger has also been evaluated in the prevention of CINV. A systematic review found seven studies that were mixed in their support of ginger for CINV, including three studies demonstrating a positive effect, two in favor but with caveats, and two trials with no effect on CINV.[238] Therefore, the use of ginger for CINV is equivocal, and further studies are required before recommending ginger for clinical use.

MANAGEMENT

OPIOIDS

Nausea and vomiting are common in patients beginning opioid therapy and generally resolve within the first several days of initiation. Often, having the patient take the opioid agent with food can minimize nausea and vomiting. Decreasing the dose or switching to a different opioid drug is another option. Patients who experience severe or repeated episodes of nausea or vomiting or both despite these interventions may benefit from scheduled doses of an antiemetic agent. The patient should be evaluated to rule out other causes of the GI symptoms. **Table 40-13** lists agents commonly used in the treatment of opioid-induced nausea and vomiting.[116,117]

In general, drugs useful in the treatment of opioid-induced nausea and vomiting include dopamine receptor antagonists, anticholinergic agents, and 5-HT_3–receptor antagonists.[153,239-241] Nausea and vomiting accompanied by abdominal distention or occurring immediately after meals may be attributed to opioid-induced gastroparesis, which may respond to metoclopramide administration before each meal and at bedtime. If the nausea and vomiting are associated with movement or are accompanied by dizziness, an anticholinergic agent or an antihistamine would be a more appropriate option.[162]

Table 40-13 Agents for the Management of Opioid-Induced Nausea and Vomiting

Class	Drugs
Anticholinergic	Scopolamine
Antihistamine	Diphenhydramine
Benzodiazepine	Midazolam
Corticosteroid	Dexamethasone
DOPAMINE ANTAGONISTS	
5-HT_3–receptor antagonist	Ondansetron
Substituted benzamide	Metoclopramide[a]
Butyrophenones	Droperidol, haloperidol
Opioid antagonist[b]	Naloxone
Phenothiazines	Prochlorperazine, promethazine[c]

[a] Also possesses peripheral activity at 5-HT_3 and 5-HT_4 receptors.

[b] When administered systemically in very low doses; may counteract analgesia.

[c] Also possesses antihistaminic and anticholinergic activity.

Ondansetron has been compared to metoclopramide for the management of opioid-induced emesis after surgery. In a study of over 1,000 patients, ondansetron 8 mg IV, ondansetron 16 mg IV, and metoclopramide 10 mg IV were evaluated for the treatment of opioid-induced emesis.[241] Control of emesis was achieved in 63%, 61%, and 48% of patients, respectively; however, there was no significant difference in nausea scores among groups. This finding is similar to other trials. Overall, it appears that ondansetron 8 mg IV is effective for the management of opioid-induced vomiting.

Methylnaltrexone, a peripheral opioid antagonist, may have the potential to treat opioid-induced nausea and vomiting. A small double-blind, randomized, placebo-controlled trial of 12 participants receiving morphine with placebo or morphine with methylnaltrexone showed that patients in the methylnaltrexone arm had a significant reduction in delayed gastric emptying as well as significantly reduced opioid subjective effects including nausea.[242] Larger, randomized controlled trials will need to be performed to address methylnaltrexone's role in treating or preventing opioid-induced nausea and vomiting.

PERIOPERATIVE AGENTS

Patients who experience PONV should limit movement and position changes, because excessive motion may exacerbate the condition. In general, any food or fluid intake by mouth should be discouraged for the first 8 hours postoperatively in patients experiencing PONV.[120] Patients who did not receive prophylactic therapy with a 5-HT_3–receptor antagonist should be treated with one of these agents postoperatively at the onset of PONV. Repeating the antiemetic used for PONV prophylaxis within 6 hours after the patient leaves the postanesthesia care unit offers no additional benefit. Instead, an antiemetic from another class should be tried. If more than 6 hours have elapsed, repeating the dose of the 5-HT_3–receptor antagonist or droperidol can be attempted; however, limited data support this practice.[192]

The effectiveness of granisetron or ondansetron for breakthrough PONV following prophylactic ondansetron has been evaluated.[243] In this trial, there were no significant differences between the granisetron and ondansetron groups in the 4-hour postoperative period. Up to a 68% complete response rate (resolution of PONV with no additional rescue medication required) was reported. A randomized, placebo-controlled trial of ondansetron 4 mg IV was conducted to evaluate PONV treatment in over 400 patients receiving inhaled anesthesia. All patients received preoperative prophylactic ondansetron. Complete response (no emesis and no rescue medication required) was similar for both the ondansetron and placebo groups at 2 hours (34% and 43%, respectively) and 24 hours (28% and 32%, respectively) after anesthesia. Patients who received repeated ondansetron doses for postoperative emesis or nausea had effects similar to those who received placebo.[244] **Table 40-14** lists antiemetic agents and their recommended doses for PONV treatment.[141,192]

Table 40-14 Agents for the Management of Postoperative Nausea and Vomiting

Drug	Dose
Dexamethasone	2–4 mg IV
Dolasetron	12.5 mg IV
Droperidol[a,b]	0.625–1.25 mg IM/IV; may give additional 1.25 mg as needed
Granisetron	0.1 mg IV
Metoclopramide[b]	10 mg IV q 4–6 hr as needed
Ondansetron	1–4 mg IV
Prochlorperazine[b]	5–10 mg IM/IV; may repeat once if needed
Promethazine[b]	6.25–25 mg IM/IV; may repeat once if needed
Tropisetron	0.5 mg IV

IM = intramuscular, IV = intravenous.

[a] Caution should be exercised when giving additional doses because of the risk of inducing cardiac arrhythmias.

[b] Repeated doses may increase the risk of extrapyramidal symptoms.

CHEMOTHERAPY

Prevention is the best management strategy for chemotherapy-induced nausea and vomiting. Although the oncology literature is replete with information regarding prevention of this drug-induced disease, data regarding the effectiveness of various management strategies are sparse. Several national groups have developed guidelines for the treatment of CINV.[160,161,237,245] The drugs and doses commonly used are listed in **Table 40-15**. If breakthrough emesis develops despite adequate prophylaxis with a 5-HT$_3$ antagonist combined with dexamethasone, therapy with an agent from a different drug class should be initiated. A single dose of a 5-HT$_3$ antagonist is expected to occupy the receptor site and maintain effectiveness for up to 24 hours, thereby obviating the need for repeat dosing.

Table 40-15 Agents for the Management of Chemotherapy-

Induced Nausea and Vomiting

For treatment of breakthrough nausea and vomiting despite the use of prophylactic antiemetics:

- Dexamethasone 12 mg IV/PO
- Dolasetron 100 mg PO
- Dronabinol 5–10 mg PO
- Granisetron 1–2 mg PO or 0.01 mg/kg (max 1 mg) IV
- Haloperidol 0.5–2 mg PO/IV
- Lorazepam 0.5–2 mg PO/ SL/IV
- Metoclopramide 10–40 mg IV
- Nabilone 1–2 mg PO
- Olanzapine 5–10 mg PO
- Ondansetron 16–24 mg PO or 8–16 mg IV
- Prochlorperazine 10 mg PO/IV or 25 mg PR
- Promethazine 12.5–25 mg PO/IV or 25 mg PR
- Scopalamine transdermal patch q 72 hr

IV = intravenous, PO = oral, PR = rectal, SL = sublingual.

Choice of a specific drug to treat CINV depends on the patient’s prophylactic regimen and his or her ability to tolerate potential adverse effects of the agent selected. Many drugs, including lorazepam, phenothiazines, metoclopramide, corticosteroids, butyrophenones, and dronabinol, have been used for the treatment of chemotherapy-induced emesis. Oral cannabinoids (i.e., dronabinol, nabilone) have also been shown to be effective in relieving CINV. Smoked marijuana, although highly touted as an effective treatment, has not been thoroughly evaluated in patients who are undergoing chemotherapy. A small, double-blind, placebo-controlled trial compared ondansetron and smoked marijuana in 13 patients who ingested ipecac syrup.[246] Ondansetron was significantly more effective than either smoked marijuana or placebo for the prevention of nausea and emesis. There was no difference in the incidence of nausea in patients treated with marijuana versus those who received placebo. Several states allow the use of marijuana for medicinal purposes. Although distributors and users can still be prosecuted under federal law, enforcement hasn’t occurred in recent years. The American Cancer Society supports the need for more scientific research on cannabinoids in patients with cancer.[247]

If a patient received a 5-HT$_3$–receptor antagonist for prophylaxis, dopamine receptor inhibitors such as phenothiazines, metoclopramide, or butyrophenones can be administered for breakthrough nausea and vomiting.[160,161,237] Olanzapine, at a dose of 10 mg orally for 3 days, has been compared to metoclopramide for breakthrough nausea and vomiting where a higher proportion of patients had no significant vomiting (70% versus 31%) and no significant nausea (68% versus 23%) with olanzapine than metoclopramide, respectively.[248] These agents should be used cautiously, however, in patients at risk for extrapyramidal effects (e.g., pediatric and young adult patients and those with underlying Parkinson disease).[249] If a patient did not receive a 5-HT_3 antagonist as prophylaxis, then postchemotherapy nausea and vomiting may be treated with one of these drugs. Before the next chemotherapy cycle, the patient's antiemetic regimen should be altered to include a 5-HT_3–receptor antagonist and dexamethasone with the addition of NK-1 RA or olanzapine if the patient experienced delayed nausea and vomiting.

MISCELLANEOUS AGENTS

A study of patients with acquired immunodeficiency syndrome (AIDS) who were newly diagnosed with *Pneumocystis (carinii) jiroveci* pneumonia evaluated the role of ondansetron in the treatment of TMP/SMX-induced nausea and vomiting.[250] Sixteen patients were treated with 1,120 mg of the trimethoprim component of parenteral TMP/SMX with plans to switch to two oral TMP/SMX double-strength tablets four times a day for a total of 21 days. Patients received ondansetron 8 mg PO every 8 hours for 25 days. Only 7 patients completed all of the planned TMP/SMX treatment. Therapy was discontinued in the others for a variety of reasons. Overall, for 16 patients who initially received TMP/SMX, 69% had a "good emetic response," defined as two or fewer emetic episodes, and 44% experienced a "good nausea response," defined as no or mild nausea. Six patients were switched to a trimethoprim–dapsone regimen and did not experience any additional emesis. It is obvious from this trial that nausea and vomiting may develop in AIDS patients receiving high-dose TMP/SMX and that it can require switching therapy or the addition of antiemetics. It is unclear what impact ondansetron provided, because there was no control group.

Erythromycin can induce nausea and vomiting in a substantial number of patients. One study evaluated the role of glycopyrrolate and longer erythromycin infusion times on the incidence of nausea and vomiting.[93] This randomized, double-blind, placebo-controlled trial studied 51 patients receiving erythromycin 500 mg IV every 6 hours infused over either 30 or 60 minutes. Patients were randomly assigned to receive either glycopyrrolate 0.1 mg IV or placebo. Nausea and vomiting were significantly reduced in patients who received the 60-minute infusion and pretreatment with glycopyrrolate.

When nausea and vomiting are due to high serum concentrations of a drug, as with digoxin, for example, it is often necessary to temporarily discontinue the medication to allow the drug concentration to decrease before restarting therapy at a lower dose.

INFORMATION FOR PATIENTS

OPIOIDS

Patients started on therapy with opioid analgesics should be warned of the likely occurrence of nausea with or without vomiting. Patients should be informed that these symptoms are generally transient and will usually subside after the first few days of therapy. The exception is nausea and vomiting that occur as a result of opioid-induced constipation, to which tolerance will not develop. Patients who will receive long-term opioid therapy should take an appropriate stimulant laxative to prevent constipation and its associated problems, including nausea and vomiting. These patients should be informed that the bowel regimen should be continued throughout the duration of opioid treatment. Patients should be told that they can take the opioid analgesic with meals to help lessen gastric irritation that can often lead to nausea, vomiting, and abdominal pain.

Patients beginning opioid therapy should be counseled regarding the specific antiemetic agent to be used if nausea, vomiting, or both occur, and a prescription for an appropriate rescue antiemetic should be provided. Patients should also be instructed to seek medical attention if the nausea and vomiting become severe or if these symptoms are accompanied by others, such as abdominal pain or fever.

PERIOPERATIVE AGENTS

Patients should be informed during the preoperative interview that the overall risk of PONV ranges from 10% to 80%. In patients with no identifiable risk factors, the PONV probability is approximately 10%. Patients should be made aware of the risk factors associated with PONV and should be questioned about their previous experiences with general anesthesia. In addition, any prior adverse drug reactions or drug-induced diseases should be documented during the preoperative evaluation.

Patients should be instructed not to eat or drink anything during the specified preoperative period (anesthesiologists have preferences regarding the specific duration of time based on the type of surgery, type and duration of anesthesia, and patient-related risk factors for PONV). Questions that the patient may have regarding the surgery should be answered, and any concerns should be addressed. Preoperative anxiety has been linked to PONV, so anything that can alleviate the patient's anxiety may reduce that risk.[120]

CHEMOTHERAPY

CINV can be a distressing drug-induced disease that can significantly affect quality of life. Clinicians and patients must understand that there are no available drugs that are effective for the prevention or treatment of nausea and vomiting in all cases. If a patient has a prescription for a scheduled antiemetic therapy at home, he or she should be advised to take that medication as instructed. Many patients feel well immediately following chemotherapy and do not have prescriptions filled promptly; others cannot afford the medications. In either case, patients may find themselves unprepared to deal with delayed nausea and vomiting if and when it occurs. Patients with persistent nausea and vomiting that interferes with oral intake should be instructed to contact their healthcare professional. Patients should be advised to seek immediate medical attention if severe symptoms of dehydration (e.g., dizziness, confusion) occur and should be advised to maintain adequate fluid intake to prevent dehydration. Good communication between the patient and healthcare provider(s) is essential to the maintenance of effective antiemetic therapy. Patients in whom nausea develops should be instructed to eat small meals and choose bland foods (crackers, flat soda, etc.) and should avoid fatty, fried, very spicy, or sweet foods. To prevent nausea, patients should be encouraged to eat foods that are cold or at room temperature, because the aroma of warm or hot foods can increase nausea.

MISCELLANEOUS AGENTS

Anyone beginning therapy with a new medication may experience nausea and vomiting. Patients should routinely be instructed to contact their healthcare providers to discuss alternative therapeutic approaches if they are unable to tolerate the new agent. In some cases, the strategies to control nausea and vomiting described above may be helpful and necessary.

Note: The authors wish to acknowledge the work of Dr. Nayahmka McGriff-Lee, who authored this chapter in a previous edition.

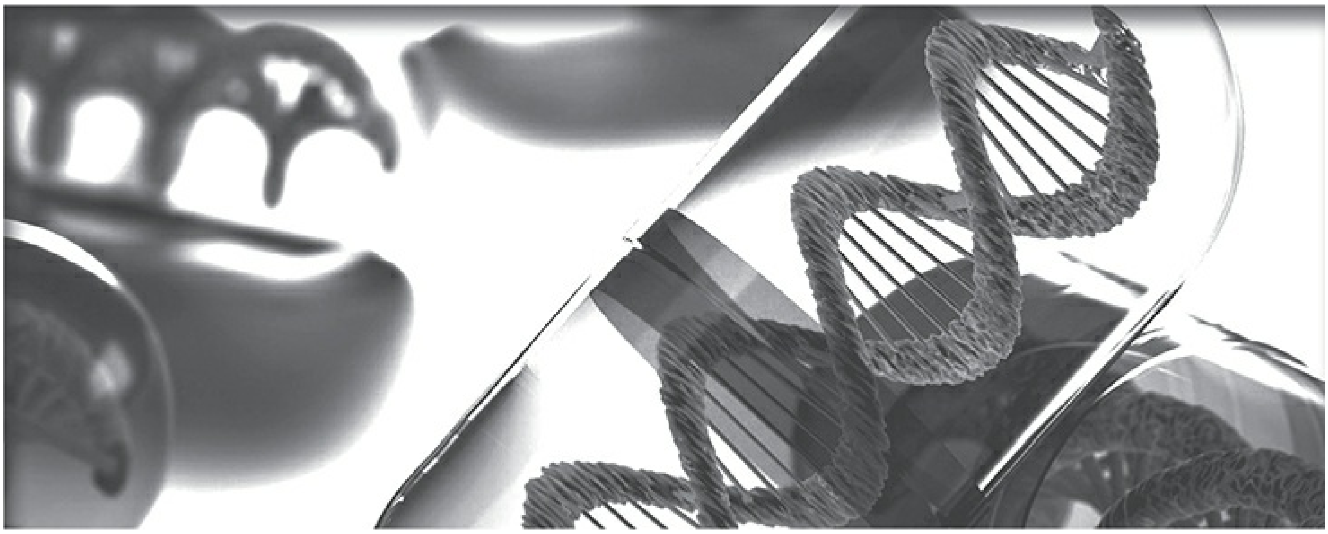
DRUG-INDUCED DISEASES OF THE KIDNEY AND FLUID & ELECTROLYTE DISORDERS

CHAPTER 41 Acute Kidney Injury

CHAPTER 42 Chronic Kidney Disease

CHAPTER 43 Syndrome of Inappropriate Antidiuretic Hormone Secretion and Diabetes Insipidus

CHAPTER 44 Acid–Base Disorders



CHAPTER 41

Acute Kidney Injury

Amy Barton Pai and Nicole M. Wegrzyn

The kidneys are a primary pathway for the elimination of drugs and toxins, and they receive 25% of cardiac output, thus increasing their exposure to circulating drugs. In addition, renal hemodynamics may be altered by drugs. These factors result in enhanced susceptibility to drug-induced injury by enhancing potential for proximal tubule cell uptake and by reducing glomerular capillary pressure.[1] Although there is no universal definition of acute kidney injury (AKI), an increase in serum creatinine concentration of 25–30% above baseline values is a useful working definition. Newer definitions exist, but are not yet universally used in the literature.[2,3] AKI occurs in up to 5% of hospitalized patients, and it has been estimated that approximately 20% of these cases are drug induced.[4] In an analysis of adverse events in hospitalized patients, kidney dysfunction accounted for 6.7% of drug-related complications.[5] The true incidence of drug-induced AKI is difficult to determine due to the lack of consistency in defining the condition.[6]

To help distinguish between differing etiologies and outcomes, AKI can be categorized as either community-acquired (CA-AKI) or hospital-acquired (HA-AKI). Common causes of HA-AKI include sepsis or other critical illnesses and exposure to contrast media or nephrotoxic medications commonly used in inpatient care. CA-AKI is characterized by a rapid decline in kidney function that occurs in the outpatient setting and is typically caused by disease and by medications that alter renal hemodynamics and reduce effective perfusion. Because of the rapid onset of AKI, uremia and fluid overload are often worse than seen in patients with chronic kidney disease. Early symptoms reported by patients include fatigue, reduced urine output, and edema, especially in the lower extremites.[7]

Recent analyses have shown that the incidence of CA-AKI is higher than the incidence of HA-AKI. Approximately 80% of those hospitalized and discharged with the AKI International Classification of Diseases (ICD)-9 fit criteria for CA-AKI.[8] Duration of hospitalization and mortality rate are lower among CA-AKI patients than in those with HA-AKI. Recovery of kidney function is incomplete in those with CA-AKI, and data show similar long-term outcomes on kidney function to patients who experience HA-AKI, with nearly 40% developing new-onset or progression of chronic kidney disease (CKD).[9-12] A recent cohort analysis of Veterans Affairs (VA) hospital patients in upstate New York found the incidence of CA-AKI to be 3.5 times higher than HA-AKI.[8] In a large cohort study performed in the United Kingdom, significantly more patients with CA-AKI received a new diagnosis of CKD within 14 months of the CA-AKI episode versus those with HA-AKI. Approximately 15% of patients with CA-AKI had no notation of renal impairment or planned follow-up at discharge.[12] A retrospective analysis of AKI admissions (335 CA-AKI and 87 HA-AKI) at a VA hospital in Kentucky found that documented outpatient nonsteroidal anti-inflammatory drug (NSAID) use was higher in the CA-AKI group than the HA-AKI (64 versus 10 patients).[10] Potential biomarkers of AKI and kidney failure are being identified and evaluated and may in the future refine our ability to predict and prevent drug-induced AKI.[13,14]

Drug-induced AKI can result from renal hemodynamic alterations leading to reduced renal perfusion, from direct toxicity to the renal tubule cells (acute tubular necrosis), from tubulointerstitial inflammation secondary to an allergic reaction (acute interstitial nephritis), from precipitation of drug crystals resulting in obstruction (nephrolithiasis), or from an immune-mediated reaction resulting in damage to the glomerulus (glomerulonephritis). The sections that follow provide additional detail regarding the agents known to cause AKI by each of these mechanisms.

HEMODYNAMIC-MEDIATED AKI

Hemodynamic-mediated AKI manifests primarily as prerenal azotemia and is the most frequently reported cause of CA-AKI.[15] Dilation of the efferent arteriole or constriction of the afferent arteriole reduces the effective perfusion of the glomerulus, thus decreasing filtration.

CAUSATIVE AGENTS

Any agent that decreases intravascular volume and renal perfusion (e.g., diuretics), constricts the afferent arteriole (e.g., NSAIDs, cyclooxygenase-2 [COX-2] inhibitors, cyclosporine) or dilates the efferent arteriole (e.g., angiotensin-converting enzyme inhibitors [ACEIs], angiotensin receptor blockers [ARBs], direct renin inhibitors) can induce hemodynamically mediated AKI when predisposing factors are present. The drugs most frequently associated with alteration of intrarenal hemodynamics are the ACEIs and NSAIDs.[16] These and other agents implicated in drug-induced AKI are included in **Table 41-1**.

EPIDEMIOLOGY

ACEIs and ARBs are frequently used to treat hypertension, reduce ventricular remodeling, and prevent progression of proteinuric kidney disease.[17] According to one report, an acute rise in serum creatinine concentration greater than three times baseline occurred in 38% of patients with unilateral renal artery stenosis who received captopril.[17] In a series of patients with no known renal artery stenosis, 6% receiving captopril had a rise in serum creatinine that warranted discontinuation of the drug.[18] Aliskiren is a direct renin inhibitor that has been investigated as an antihypertensive and renoprotective agent.[88,89] Short-term studies (2–6 months) have not demonstrated increased risk of elevation of serum creatinine concentrations with aliskiren combined with losartan or ramipril versus losartan or ramipril alone.[89,90] However, in a large multicenter trial of patients with diabetic nephropathy, two patients in the aliskiren plus losartan combination group developed acute kidney failure, versus none who received the ARB alone.[90]

NSAIDs are used extensively worldwide. An estimated 36 million Americans use nonprescription analgesics on a daily basis.[21,91] NSAIDs and COX-2 inhibitors are among the most frequently prescribed agents in the United States.[92,93] Adverse kidney effects secondary to NSAID use occur in 1–5% of patients and account for an estimated 37% of drug-associated AKI cases.[16,21] COX-2 inhibitor–induced AKI has been documented in approximately 240 reports to the U.S. Food and Drug Administration and in 20 published case reports.[22,94-96] A study completed while rofecoxib was still available in the United States examined the incidence of adverse kidney experiences with that agent when used for osteoarthritis versus ibuprofen, diclofenac, and nabumetone.[97] The incidence of adverse renovascular events, including the development of edema, heart failure, hypertension, and elevated serum creatinine were similar between drugs, with no reported cases of fulminant AKI. However, this trial excluded high-risk patients with CKD. There have been no prospective studies linking NSAID use to AKI or other renal complications. The majority of data have been from large cohort studies in the United Kingdom, Europe, and Canada—countries that have nationalized healthcare and database infrastructure that allows linkage of outpatient and inpatient data. All of the existing literature has examined prescription NSAID use, which underscores the need to capture nonprescription NSAID exposure as well. Previous studies have also relied on accurate coding of AKI admissions which likely limits assessment of CA-AKI because patients may not be admitted.[98,99] Studies evaluating estimated glomerular filtration rate decline are limited by inclusion of relatively young patients with intact kidney function.[100,101] Because the major causes of CA-AKI are hypovolemia and clinical situations or medications that can affect renal blood flow, an understanding of the relationships between NSAID use and drug-induced hemodynamic changes is important in the identification of at-risk populations and the design of effective methods to minimize NSAID exposure. Several authors have identified varying levels of risk for AKI associated with what has been referred to as the "triple whammy" (concomitant exposure to diuretics, renin angiotension system inhibitors, and NSAIDs).[102-104] A nested case-control study utilizing Tennessee Medicaid enrollees represents the only published U.S. data to date.[27] The study evaluated the association of NSAID use on ICD-9 coded AKI hospitalizations and serum creatinine parameters. NSAID use was higher among AKI cases versus population controls. Use of NSAIDs increased the risk of AKI by 58% (RR 1.58, 95% CI 1.34–1.86), and the authors specifically reported that higher doses of ibuprofen (defined as doses greater than or equal to the maximum recommended starting dose) were associated with higher risk of developing AKI.[27]

Table 41-1 Agents Implicated in Drug-Induced Acute Kidney Injury

Drug	Incidence	Level of Evidence[a]
ACUTE INTERSTITIAL NEPHRITIS		
Allopurinol[1]	NK	C
5-aminosalicylic acids[64]	NK	C
β-lactam antibiotics[1]	NK	C
Ciprofloxacin[65]	NK	C
Erythromycin[66]	NK	C
H_2-receptor antagonists[1]	NK	C
Lithium[67]	NK	B
Loop diuretics[1]	NK	C

NSAIDs[1,68]	NK	C
Phenytoin[69]	NK	C
Proton pump inhibitors[70]	NK	C

ACEI = angiotensin-converting enzyme inhibitor, ARB = angiotensin receptor blocker, COX-2 = cyclooxygenase-2, NK = not known, NSAID = nonsteroidal anti-inflammatory drug.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Incidence is higher when contemporary definitions of AKI are applied.

[c] Incidence is dose-dependent.

[d] Patients with unilateral renal artery constriction.

MECHANISMS

Mechanisms of drug-induced AKI are listed in **Table 41-2**. ACEIs and ARBs affect renal hemodynamics by selectively dilating the efferent arteriole. In patients with adequate renal perfusion and no disease-specific risks, dilation of the efferent arteriole rarely compromises the GFR.[105] However, in the setting of reduced renal perfusion, as might occur in patients with hypovolemia or heart failure, adequate glomerular filtration is maintained by activation of the renin–angiotensin–aldosterone system (RAAS). The resultant constriction of the efferent arteriole allows glomerular capillary pressure to be maintained. In these “renin-dependent” states, inhibition of the RAAS by ACEIs or ARBs may result in a precipitous drop in glomerular filtration. In addition, decreasing renal perfusion increases the risk of kidney ischemia and necrosis.[106]

Table 41-2 Mechanisms of Drug-Induced Acute Kidney Injury

Drug	Mechanism
ACEI, ARBs[17-19]	Efferent arteriole vasodilation especially when renin-angiotensin-aldosterone system–dependent vasoconstriction is present
Acyclovir,[74] sulfadiazine,[81] indinavir[78,79]	Supersaturation of the urine with solute, resulting in crystal formation
Aminoglycosides[28-32]	Saturable accumulation of aminoglycosides in the S1 and S2 segments of the proximal tubule, leading to inhibition of phospholipases and tubular cell death
Amphotericin B[28,33-37]	Afferent arteriole vasoconstriction and altered tubule cell permeability leading to cell lysis
Cisplatin[58-60]	Tubular cell toxicity secondary to binding to mitochondrial DNA, impairing cellular function and inducing apoptosis
Lithium[70]	Development of minimal-change disease and focal segmental glomerulosclerosis
NSAIDs, COX-2 inhibitors[21-27]	Hemodynamic: Inhibition of prostaglandin-dependent afferent arteriole vasodilation Acute interstitial nephritis: T cells infiltrate the kidney interstitium, imitating an immunologic response
Radiocontrast media[40-57]	Afferent arteriole vasoconstriction and reactive oxygen species–mediated tubular toxicity

ACEI = angiotensin-converting enzyme inhibitor, ARB = angiotensin receptor blocker, COX-2 = cyclooxygenase-2, DNA = deoxyribonucleic acid, NSAID = nonsteroidal anti-inflammatory drug.

COX-2 inhibitors and nonselective NSAIDs inhibit the enzymatic activity of COX, blocking the formation of autocoid prostaglandins from arachidonic acid. Two isoforms of COX have been identified.[24] COX-1 is constitutively expressed and mediates homeostatic functions such as gastrointestinal cytoprotection, platelet aggregation, and renal perfusion.[24] COX-2 is considered to be an inducible isoform that channels the production of prostaglandins responsible for pain and inflammation.[21] Conventional NSAIDs inhibit the activity of both COX-1 and COX-2 isoforms. The COX-2 inhibitors specifically block the enzymatic activity of the inducible COX-2 isoform of COX. The therapeutic benefits of the NSAIDs are attributed to COX-2 inhibition, whereas the adverse gastrointestinal, platelet, and kidney effects are attributed to COX-1 inhibition.[21,24] The primary kidney effects of nonselective COX inhibition are vasoconstriction of the afferent arteriole, increased sodium reabsorption, and decreased potassium excretion.[25] Data from human and animal studies confirm that COX-2 is constitutively expressed in the kidney and its expression is increased in states of sodium restriction.[21,107,108] Current data suggest that COX-2 is essential to the maintenance of renal hemodynamics because of prostaglandin-mediated vasodilation of the afferent arteriole.[109] COX-2 expression also appears to be mediated by angiotensin II.[26] The renal effects of COX-2 inhibitors appear to be similar to those of NSAIDs and, in high-risk patients can lead to AKI, necessitating cautious use in certain populations.[25,97,110]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Signs and symptoms associated with AKI are included in **Table 41-3**. Patients with AKI secondary to ACEI or ARB therapy frequently have experienced an acute hypovolemic insult with an associated rise in serum creatinine concentration.[111] Patients may have laboratory findings consistent with prerenal azotemia but rarely present with symptoms of fulminant uremia. Kidney dysfunction due to an ACEI or ARB is commonly identified during routine laboratory monitoring in the outpatient setting. Elevations in serum creatinine concentration typically occur within 2 weeks after the initiation of these drugs and can be more pronounced in patients with known risk factors (see below).[112] Differential diagnosis includes other causes of prerenal azotemia, including hypovolemia (e.g., excessive diuresis, vomiting, diarrhea), heart failure, cirrhosis, or sepsis (**Table 41-4**). Acute renal compromise can occur with a single dose of an NSAID, and the risk has been shown to escalate with increasing doses and duration of use.[25,27,113] Patients typically present with elevated serum creatinine and blood urea nitrogen concentrations, weight gain, and diminished urine output. Patients receiving NSAIDs may also present with kidney dysfunction following any event that compromises renal blood flow (e.g., heart failure, gastroenteritis). NSAIDs inhibit prostaglandin-mediated renin release, impairing the excretion of potassium, and thus hyperkalemia is also commonly found in patients presenting with NSAID-induced AKI.[113] Irreversible kidney failure due to prolonged renal ischemia can occur in high-risk patients in whom kidney dysfunction is not recognized.[114]

Patients with COX-2 inhibitor–induced AKI present with a clinical picture similar to NSAID-induced AKI. Hyperkalemia, volume overload, and hyponatremia are common features of COX-2 inhibitor–induced AKI.[95] The duration of COX2–inhibitor use before presenting with AKI has varied within the range of 6–21 days.[95]

Table 41-3 Signs and Symptoms Associated with Drug-Induced Acute Kidney Injury

General

- Costovertebral-angle tenderness
- Edema
- Elevated serum creatinine concentration

- Fever
- Hypertension
- Malaise
- Rapid weight gain

Acute interstitial nephritis

- Arthralgias
- Eosinophilia
- Eosinophiluria
- Proteinuria
- Pyuria
- Skin rash

Acute tubular necrosis

- Magnesium wasting (cisplatin/carboplatin-induced)
- Oliguria

Glomerulonephritis

- Foamy urine
- Marked facial and lower extremity pitting edema
- Oliguria
- Proteinuria
- Skin rash

Nephrolithiasis

- Hematuria
- Renal colic

Table 41-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Acute Kidney Injury

For patients with suspected drug-induced AKI

- Autoimmune glomerular disease
- Chronic kidney disease
- Cirrhosis
- Heart failure exacerbation
- Hypovolemia
- Infection
- Sepsis

For patients with suspected drug-induced nephrolithiasis

- Abdominal aortic aneurysm
- Appendicitis
- Ectopic pregnancy
- Pyelonephritis

AKI = acute kidney injury.

RISK FACTORS

Table 41-5 and Table 41-6 provide an overview of risk factors for drug-induced AKI. Acute hypovolemia secondary to vomiting, diarrhea, or excessive diuresis are common precipitating events for the development of AKI secondary to ACEI or ARB therapy, especially in patients over the age of 80 years.[105,112,115] The risk of an acute increase in serum creatinine concentration >30% above baseline with renin–angiotensin system blockade is markedly increased in patients with CKD and in conditions in which reduced effective plasma volume leads to renal hypoperfusion including, most commonly, volume depletion, heart failure, or cirrhosis.[106] In patients with severe atherosclerotic cardiovascular disease or those who are heavy smokers, bilateral renal artery stenosis should be considered as a potential cause of hemodynamic-mediated AKI when other more obvious causes are not present.[97] Concomitant therapy with NSAIDs, diuretics, or both has been identified as a predisposing factor for ACEI–induced AKI.[105,116] Longer-acting ACEIs (e.g., lisinopril) have been associated with a higher incidence of AKI, as compared with shorter-acting agents (e.g., captopril).[19]

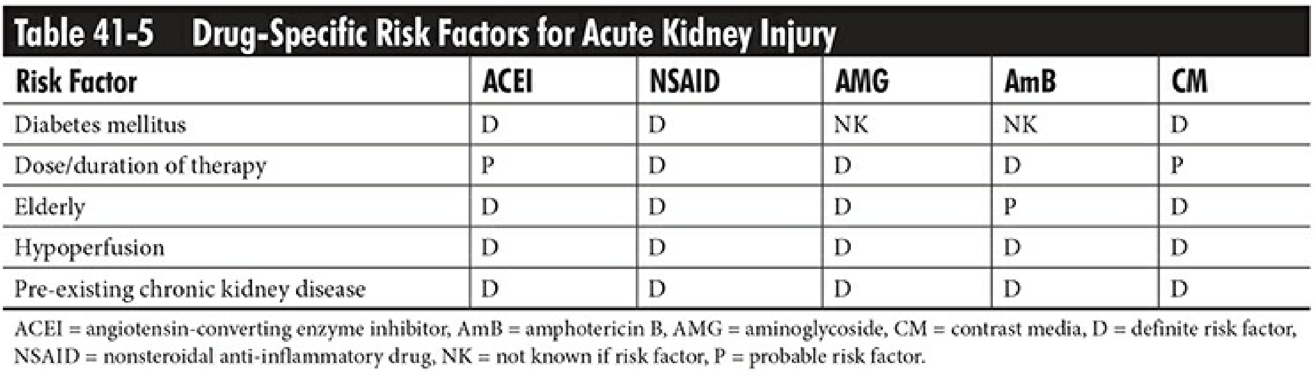

Table 41-5 Drug-Specific Risk Factors for Acute Kidney Injury

Risk Factor	ACEI	NSAID	AMG	AmB	CM
Diabetes mellitus	D	D	NK	NK	D
Dose/duration of therapy	P	D	D	D	P
Elderly	D	D	D	P	D
Hypoperfusion	D	D	D	D	D
Pre-existing chronic kidney disease	D	D	D	D	D

ACEI = angiotensin-converting enzyme inhibitor, AmB = amphotericin B, AMG = aminoglycoside, CM = contrast media, D = definite risk factor, NSAID = nonsteroidal anti-inflammatory drug, NK = not known if risk factor, P = probable risk factor.

Table 41-6 Risk Factors for Drug-Induced Acute Kidney Injury

- Concomitant administration of nephrotoxins
- Elderly
- Hemodynamic dose-dependent effects
- Known allergic response to agent (acute interstitial nephritis)
- Pre-existing chronic kidney disease
- Prolonged therapy with nephrotoxins
- Renin-dependent disease states
  - Cirrhosis
  - Heart failure
  - Hypovolemia
  - Overdiuresis

Prostaglandin inhibition by nonselective NSAIDs and COX-2 inhibitors rarely compromises kidney function in healthy patients receiving therapeutic doses of these agents on a short-term basis (e.g., 7–10 days).[117] Patients at risk for AKI are those with disease states that reduce renal perfusion and require a compensatory increase in renal prostaglandins to promote vasodilation of the afferent arteriole and maintain adequate glomerular capillary pressure and filtration.[118] Elderly patients with age-related CKD are at high risk for drug-induced AKI, and the use of NSAIDs may increase the risk by up to 58% in patients older than 65 years.[27] A greater risk of AKI has also been associated with total daily doses of ibuprofen >1,200 mg.[27] Reported risk factors for COX2 inhibitor–induced AKI are similar to those of NSAID-induced AKI, including age >60 years, CKD, and concomitant therapy with loop diuretics.[95] ACE inhibition up-regulates COX-2 expression, and patients dependent on angiotensin II for glomerular perfusion may be at increased risk for AKI when receiving concomitant ACEI therapy.[26] The development of kidney failure may also be associated with doses exceeding the labelling recommendation for COX-2 inhibitors.[23]

MORBIDITY AND MORTALITY

Mortality secondary to AKI induced by an ACEI or ARB alone is low. Morbidity has not been well characterized but may be substantial given the high prevalence of ACEI and ARB use in high-risk populations such as those with CKD and heart failure.[112] Analysis of the Studies of Left Ventricular Dysfunction data demonstrated a 4% greater risk of decreased kidney function (defined as a serum creatinine concentration increase ≥0.5 mg/dL from baseline) in patients receiving enalapril 2.5–10 mg twice daily as compared with a placebo-treated group.[119]

The majority of NSAID-induced AKI cases resolve promptly after discontinuation of the offending agent; however, hospitalization may be necessary to provide supportive management, particularly if volume overload or hyperkalemia is present. Rarely, hemodynamic-mediated deterioration of kidney function can lead to irreversible, long-term kidney failure, necessitating dialysis.[25] The majority of reported cases of COX-2–induced AKI have resolved within 2–8 days after discontinuing the offending agent.[22,95] Some patients have required short-term hemodialysis to manage hyperkalemia and volume overload.[95]

PREVENTION

Approaches to help prevent drug-induced AKI are outlined in **Table 41-7**. With ACEIs and ARBs, the primary strategy for preventing acute elevations in serum creatinine concentration is to ensure that patients have an adequate plasma volume before initiating therapy. Diuretics should be withheld or the dose reduced before initiating therapy with an ACEI or ARB.[105] Therapy should be initiated at low doses, which can then be slowly titrated upward after evaluation of serum creatinine concentration. Serum creatinine concentration should be monitored every 2 weeks until it stabilizes and after any dose increase.[105]

Table 41-7 Approaches to Help Prevent Drug-Induced Acute Kidney Injury

- Avoid use of drugs associated with AKI in patients with risk factors listed in Tables 41-5 and 41-6
- Avoid concurrent use of other agents that affect renal hemodynamics
- Avoid overdiuresis
- Avoid concomitant exposure to nephrotoxins
- Consider once-daily dosing with aminoglycosides (amikacin, gentamicin, tobramycin)
- Counsel patients regarding increased risk if volume depletion occurs and need to maintain adequate fluid intake
- Consider preferential use of lipid-based products (amphotericin B)
- Consider preferential use of nonionic, iso-osmolar radio contrast media
- Dose reduction (drugs with hemodynamic effects)
- Limit duration of therapy for drugs associated with AKI, when possible
- Maintain adequate hydration
- Monitor kidney function closely in high-risk patients
- Prophylaxis with *N*-acetylcysteine or isotonic sodium bicarbonate infusion in patients at high risk for radiocontrast media-induced AKI
- Start at lowest dose (drugs with hemodynamic effects)

AKI = acute kidney injury.

Avoiding NSAID use in patients with CKD and in other high-risk populations prevents most cases of AKI associated with these drugs. A serum creatinine concentration >1.7 mg/dL has been identified as a significant risk factor for the development of AKI.[16] If NSAIDs must be used in these populations, minimum effective doses for short durations (3–5 days) should be used or alternative agents (e.g., acetaminophen or narcotic analgesics) should be considered.[120] If NSAIDs are used for longer periods, monitoring should include measurement of serum sodium, potassium, blood urea nitrogen, and creatinine concentrations within 1–3 weeks of therapy initiation and then every 3–6 months thereafter.[120] NSAIDs should be promptly discontinued if elevations in serum creatinine, blood urea nitrogen, or potassium concentration occurs. Concomitant therapy with other agents affecting renal hemodynamics including diuretics, ACEIs, and ARBs should be avoided.[105] Patients using nonprescription NSAIDs should be counseled regarding risk factors for NSAID-induced AKI.

MANAGEMENT

Initiation of therapy with an ACE inhibitor or ARB is frequently associated with an increase in serum creatinine concentration, especially in patients with CKD. This rise is most likely due to reversal of glomerular hyperfiltration by the remnant nephrons and subsequent reduced glomerular capillary pressure from dilation of the efferent arteriole.[112] If the rise in serum creatinine concentration is <30% of baseline, the ACEI or ARB can be continued. A rise in serum creatinine concentration >30% above baseline can initially be managed by attempting a 50% dose reduction of the ACEI or ARB. If the patient is already receiving the lowest dose of the drug and the rise in serum creatinine concentration persists for more than 4 weeks, the ACEI should be discontinued and the patient should be treated with other antihypertensive agents.[97] AKI associated with ACEIs and ARBs is rapidly reversible, provided that blood flow to the kidney was not impaired long enough to cause irreversible ischemic injury.[105] NSAIDs and other agents that affect renal hemodynamics should be withheld, and supportive measures, such as volume repletion, should be initiated when patients first present. Instituting these measures promptly will typically reverse kidney dysfunction within 72–96 hours; however, resolution may take up to 1 week.[25] Hyperkalemia may also be present in patients with ACEI- or ARB-induced AKI, especially in older patients with CKD, and should resolve spontaneously after fluid resuscitation and restoration of glomerular filtration.[116,121] Concurrent therapy with potassium supplements, potassium-sparing diuretics, or NSAIDs increases the risk of hyperkalemia.[121] Patients with serum potassium concentrations >5.5 mEq/L who have not responded to fluid resuscitation may require treatment with sodium polystyrene sulfonate (15–60 g repeated every 4 hours if needed) to enhance gastrointestinal potassium elimination. ACEIs or ARBs may be restarted at low doses in patients who have recovered from AKI when there is a compelling indication.[122] Serum creatinine and potassium concentrations should be re-evaluated 1–2 weeks after resuming therapy with the ACEIs or ARBs.

The primary management for NSAID-induced AKI is discontinuation of the culprit agent. Administration of intravenous or oral fluids can hasten recovery of renal perfusion. Nonemergent hyperkalemia (serum potassium concentration <6 mEq/L) can be managed with oral potassium exchange resins. If hyperkalemia becomes symptomatic (e.g., electrocardiogram changes) or symptomatic uremia develops, the patient should be hospitalized for acute treatment.

INFORMATION FOR PATIENTS

Patients with known risk factors for AKI, including CKD, age >80 years, heart failure, or any combination of these should be instructed to notify their healthcare provider should they notice reduced urine output or edema after therapy with an ACEI or ARB is begun or after an increase in dose.[108] Patients should also be advised to notify their healthcare provider if any intercurrent illness develops that may decrease circulatory volume (i.e., vomiting, diarrhea, heart failure exacerbation), as these reduce effective perfusion of the kidney.

Patients with CKD or other risk factors for AKI should be advised to avoid NSAIDs and COX-2 inhibitors, and alternative therapies should be discussed. If alternatives cannot be used and NSAID or COX-2 inhibitor therapy is initiated, patients should limit use to the shortest duration at the lowest possible dose. Patients should further be advised to have serum creatinine concentrations measured within 1–3 weeks and to monitor weight and blood pressure. Patients should be counseled to notify a healthcare professional if hypertension develops or worsens or if they experience weight gain, edema, or decreased urine output.

ACUTE TUBULAR NECROSIS

Acute tubular necrosis (ATN) can be caused by prolonged renal ischemia or by direct toxicity to the renal tubules. Drug-induced decreases in renal perfusion, as described previously, can lead to ischemia and ATN if not recognized or treated promptly.[123] Drugs can also cause direct toxicity to the renal tubules through a variety of mechanisms, including alteration of cellular function, hyperosmotic fluid shifts, and disruption of the cell membrane.[6]

CAUSATIVE AGENTS

Many drugs can induce direct tubular toxicity through a variety of mechanisms. Aminoglycosides are frequently administered antimicrobials associated with ATN, and amphotericin B (desoxycholate or conventional) is a polyene antifungal agent also associated with a high incidence of nephrotoxicity. Delivery of amphotericin B in lipid-based systems has been used to limit amphotericin B–induced ATN. Current lipid-based amphotericin B products include amphotericin B lipid complex, liposomal amphotericin B, and amphotericin B colloidal dispersion.

In patients with kidney impairment, high-osmolality contrast media have been shown to be more nephrotoxic than low-osmolality products.[42,124] Nonionic, monomeric low-osmolality contrast media do not appear to improve kidney tolerance as compared with ionic low-osmolality contrast media.[30] In nondiabetic patients with normal kidney function, low-osmolality contrast media do not offer a clinical advantage over high-osmolality contrast media and are significantly more expensive.[42]

Cisplatin is a chemotherapeutic agent used in oncology regimens for numerous malignancies and is associated with dose-dependent ATN. Colistin, a polymyxin antibiotic, has historically been implicated in ATN, leading to diminished popularity between the 1970s and 1990s. Emergence of extensively drug-resistant bacteria has prompted a resurgence of colistin use.[125]

Table 41-1 provides additional information regarding drugs known to cause ATN.

EPIDEMIOLOGY

Aminoglycoside-induced ATN is reported to occur in 5–25% of treated patients.[28] Variability in the reported incidence is likely the result of variation in the definition of nephrotoxicity, patient population studied, and duration of therapy.[118]

Nephrotoxicity (defined as a doubling of serum creatinine concentration) is a serious, dose-limiting adverse event associated with the use of conventional amphotericin B. The incidence of nephrotoxicity is reported to be as high as 65%.[126] In contrast, the incidence of nephrotoxicity is estimated to be 15–25% with newer lipid-based amphotericin B formulations.[126] Contemporary definitions of AKI detect more potential cases, yielding a higher incidence of liposomal amphotericin-B induced AKI than previously thought (54.8%).[127]

Two types of radiocontrast media, high osmolality and low osmolality, are currently marketed. High-osmolality contrast media are associated with greater reduction in renal blood flow and glomerular filtration rate than the low-osmolality preparations.[40] The incidence of contrast media-induced nephrotoxicity in patients without risk factors is reported to be 0–10%.[41,42] In patients with CKD, the risk is much higher, ranging from 40% to 50%.[41,43] The true incidence in high-risk populations is difficult to establish because diagnostic criteria are not well defined and vary significantly between studies.[44]

Nephrotoxicity related to cisplatin and other platin-containing compounds is dose related. Initial experiences with single doses of cisplatin resulted in the development of azotemia in approximately 25% of patients.[45] Since then, nephrotoxicity rates have been reduced to approximately 10% by lowering doses and slowing infusion rates. High-dose cisplatin (200 mg/m^2) is associated with nephrotoxicity rates approaching 30%.[45] Carboplatin is associated with less nephrotoxicity because the drug is more soluble, chemically stable, and binds more slowly to plasma proteins.[45] The incidence of AKI and associated rise in serum creatinine concentration in patients receiving carboplatin is approximately 6%. The incidence of nephrotoxicity associated with colistin is 43–45%.[173,174] Development of acute renal insufficiency occurs in a dose-dependent manner.[173]

MECHANISMS

In animal models, aminoglycosides have been shown to accumulate by a saturable process within endosomal and lysosomal vacuoles in epithelial cells lining the S1 and S2 segments of the proximal tubule.[29] This lysosomal accumulation inhibits phospholipases, causing formation of phospholipid-protein aggregates known as myeloid bodies, which contribute to cell death and tubular necrosis.[124]

The pathophysiology of amphotericin B-induced nephrotoxicity includes renal arterial vasoconstriction and a direct interaction with the epithelial cell membrane of the distal tubule. Several in vitro experiments revealed that amphotericin B alters cell permeability, allowing leakage of cellular constituents, followed by cell lysis and death. Infusion of amphotericin B through a peripheral vein or directly into the renal artery of animals resulted in an increase in vascular resistance and reduction in renal blood flow. These mechanisms lead to a decrease in the glomerular filtration rate as well as tubular dysfunction.[33]

Compromised renal hemodynamics and direct proximal tubular toxicity are the primary mechanisms for contrast media-induced nephrotoxicity.[42,44] Intrakidney perfusion is reduced after exposure to contrast media, and several known mediators of vasoconstriction are released, including calcium, adenosine, endothelin, and oxygen-free radicals.[68] Direct tubular toxicity has been associated with proximal tubule cell uptake of contrast media by lysosomal vacuolization.[42,44,46]

The primary mechanism of cisplatin-induced nephrotoxicity is proximal tubule cell damage and necrosis as a result of binding to mitochondrial DNA and impaired cellular energy functions.[47]Apoptosis has been identified as another potential mechanism for cell death associated with cisplatin.[128]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Aminoglycoside-induced nephrotoxicity manifests clinically as nonoliguric kidney failure, with an average rise in serum creatinine concentration of 2 mg/dL and a hypo-osmolar urinary output typically occurring after 5–7 days of treatment.[28,129,130] Urinary markers such as β_2-microglobulin are sensitive indicators of aminoglycoside-induced nephrotoxicity, but patients with urinary β_2-microglobulin may not have clinically relevant toxicity.[165] Conditions to consider in the differential diagnosis of aminoglycoside-induced nephrotoxicity should include sepsis and exposure to other nephrotoxic agents.

An extensive retrospective analysis of amphotericin B-induced nephrotoxicity in adult patients with normal baseline kidney function has been published.[34] The median interval from drug exposure to nephrotoxicity was 7 days. Thirteen percent of patients had mild nephrotoxicity (defined as a 50% increase in serum creatinine concentration), 12% had moderate-to-severe nephrotoxicity (defined as a doubling of serum creatinine concentration to ≥2 mg/dL), and 3% had severe nephrotoxicity (defined as a tripling of serum creatinine concentration to ≥3 mg/dL).[34] As with aminoglycoside-induced nephrotoxicity, conditions to consider in the differential diagnosis of amphotericin-induced nephrotoxicity include sepsis and exposure to other nephrotoxic agents.[35]

Contrast media-induced nephrotoxicity—most frequently defined as a 25% or greater increase in serum creatinine concentration from baseline that occurs within 24–72 hours after the administration of contrast media—is typically nonoliguric and reversible.[46,50,51] Serum creatinine concentrations typically reach peak values at 3–5 days, depending on baseline kidney function.[42,44,46,51] Conditions to consider in the differential diagnosis of contrast media-induced nephrotoxicity should include exposure to other nephrotoxic agents (e.g., aminoglycosides, ACEIs, or ARBs), hypotension, and renal artery thrombosis after an invasive procedure has been performed.

Treatment with cisplatin commonly results in a 20–40% reduction in the glomerular filtration rate.[58] Serum creatinine concentrations typically peak within 10 days after the administration of cisplatin and may remain elevated for up to 3 weeks.[45] Magnesium wasting and hypomagnesemia occur in up to 50% of patients with cisplatin-induced nephrotoxicity and may persist after the cessation of therapy.[59] Conditions to consider in the differential diagnosis should include exposure to other drugs with direct tubular toxicity (e.g., aminoglycosides) and tumor lysis syndrome.

RISK FACTORS

Risk factors associated with aminoglycoside-induced nephrotoxicity include age >50 years, pre-existing kidney dysfunction, volume depletion, hypotension, cirrhosis, diabetes, treatment duration ≥3 days, and concomitant use of other nephrotoxic agents.[131] Serum concentrations of aminoglycosides are not predictive for the development of aminoglycoside-induced nephrotoxicity.[30] Measurement of peak serum concentrations is commonly used to ensure adequate antibacterial efficacy for this concentration-dependent class of antibiotics. Trough serum concentrations reflect the adequacy of renal elimination, with high concentrations reflective of impaired clearance requiring an extension of the dosing interval.[28]

Risk factors for amphotericin B-induced nephrotoxicity include mean daily doses ≥35 mg for at least 7 days, male sex, weight ≥90 kg, CKD, increasing age, use of ACEI, use of diuretics, and the concomitant use of other nephrotoxic agents.[34,127]

The most prominent risk factor for contrast media-induced nephrotoxicity is pre-existing reduced kidney function.[42,46] Patients with diabetes mellitus and reduced kidney function have the highest risk of contrast media-induced nephrotoxicity with an incidence as high as 50% in some studies.[43,44] The risk in patients with diabetes mellitus and normal kidney function has been reported to be only slightly higher (8–16% incidence) than in nondiabetic patients.[43,46] The volume of contrast media administered has been correlated with the development of contrast media-induced nephrotoxicity, especially in patients with diabetes mellitus and CKD, and efforts should be made to minimize the volume of contrast media administered to these patients.[40,50] Other potential risk factors that have not been as well established include concurrent use of drugs that affect renal hemodynamics (e.g., NSAIDs and ACEIs), intravascular volume depletion, heart failure, multiple contrast procedures, and multiple myeloma.[40,46,50,51]

The primary risk factor for cisplatin-induced nephrotoxicity is the dose of drug administered. Doses ranging from 50 mg/m^2 to 75 mg/m^2 are generally associated with reversible kidney dysfunction, whereas doses ≥100 mg/m^2 are frequently associated with AKI and marked ATN.[59] Ultrafilterable platinum concentration is positively correlated with intensity of renal dysfunction.[166,167]

MORBIDITY AND MORTALITY

Progression of aminoglycoside-induced nephrotoxicity to dialysis-dependent kidney failure is rare, and tubular injury is usually reversible after discontinuing therapy.[31] In one retrospective review of patients treated with an aminoglycoside, 7.3% were found to have aminoglycoside-induced nephrotoxicity and 0.2% had significant nephrotoxicity requiring hemodialysis.[32]

The incidence of mortality with amphotericin B-induced nephrotoxicity is three times higher in patients requiring hemodialysis as compared with those not requiring hemodialysis.[35] In a retrospective review of patients receiving amphotericin B for suspected or proven aspergillosis, a doubling of serum creatinine concentration was noted in 53% of patients and hemodialysis was initiated in 15% of patients.[35] The incidence of nephrotoxicity is consistently higher in bone marrow and solid organ transplant recipients. Only patients receiving cyclosporine, aminoglycosides, foscarnet, or other nephrotoxins concomitantly with amphotericin B required hemodialysis.[36]

Permanent kidney impairment, evidenced by serum creatinine concentrations that do not return to baseline, occurs in 30% of patients with amphotericin B-induced nephrotoxicity. Approximately 10–15% of patients with contrast media-induced nephrotoxicity require long-term dialysis.[52,126]

AKI secondary to cisplatin is generally reversible with supportive care, including vigorous hydration and intermittent dialysis as necessary.[59] Chronic kidney disease associated with cisplatin may occur and is characterized by polyuria and hypomagnesemia.[124] Repeated courses of cisplatin therapy can also result in irreversible kidney failure.[59]

PREVENTION

AMINOGLYCOSIDES

Although administration of aminoglycosides in a once-daily dose was thought to decrease the risk of tubular aminoglycoside accumulation, meta-analyses of clinical trials have failed to demonstrate increased safety with this approach.[132,133] Some data highlight the importance of circadian variation in the glomerular filtration rate and subsequent exposure of tubular cells to aminoglycoside.[134] Administration of gentamicin between midnight and 7 a.m. was more likely to cause nephrotoxicity than administration during other times. Coadministration of polyaspartic acid, pentoxifylline, daptomycin, and various antioxidants with aminoglycosides has been shown to decrease aminoglycoside-induced nephrotoxicity in animals, but there has been no clinical validation in humans.[31]

AMPHOTERICIN B

The successful treatment of certain invasive fungal infections requires the use of high doses of amphotericin B over prolonged periods. Drug dose and duration of treatment are independently associated with increased risk of amphotericin B-induced nephrotoxicity. The lipid-based formulations including amphotericin B lipid complex, amphotericin B colloidal complex, and liposomal amphotericin B are associated with lower incidences of nephrotoxicity and allow the delivery of larger doses of the drug for longer periods.[38,135] The beneficial effects of lipid-based formulations are thought to be related to an increased reticuloendothelial system clearance of amphotericin B and consequent reduced delivery to the kidney. Administration of 150–250 mEq of sodium (1–1.6 L normal saline) per day has been shown to minimize azotemia associated with amphotericin B by altering the tubuloglomerular feedback response.[39,171]

RADIOCONTRAST MEDIA

Numerous prophylactic interventions have been proposed to prevent contrast media-induced nephrotoxicity. Hydration with 0.45% sodium chloride solution at a rate of 100 mL/hr for 4 hours before and 8–12 hours after the administration of contrast media is recommended.[46,50] All medications known to adversely affect renal hemodynamics, including NSAIDs, ACEIs, ARBs, and diuretics should be discontinued 24–72 hours before the procedure, whenever possible.[50] Mannitol and loop diuretics have been considered for prophylaxis because of their ability to increase urinary flow rates and possibly limit contact of contrast media with the tubules. However, these agents have been associated with an increased risk of contrast media-induced nephrotoxicity, as compared with hydration alone, and are not recommended for prophylaxis.[54]

Studies investigating the potential nephroprotective effect of theophylline, an adenosine antagonist, are equivocal.[136,137] A study of 39 patients, including 17 with CKD, randomly assigned subjects to receive theophylline 5 mg/kg or placebo (normal saline) given 45 minutes before the administration of contrast media.[136] In patients with CKD, the glomerular filtration rate decreased significantly in the placebo group but not in the theophylline-treated group. Another study examined the effects of theophylline (as aminophylline) and dopamine on the prevention of contrast media-induced nephrotoxicity (defined as an increase in serum creatinine concentration >25% above baseline) after coronary angioplasty in patients with CKD.[137] Sixty patients were randomly assigned to receive either saline hydration, aminophylline 4 mg/kg followed by a continuous infusion of 0.4 mg/kg/hr plus saline hydration, or dopamine 2.5 mcg/kg/min plus saline hydration. No significant difference in the incidence of contrast media-induced nephrotoxicity was found among the three groups.

Calcium-channel blockers have been shown to reverse hemodynamic changes induced by contrast media.[55] A clinical trial of nitrendipine, a dihydropyridine calcium-channel blocker, reported improved renal blood flow and reduction in tubular enzymes measured in urine when 20 mg was administered 1 day before and 2 days after the administration of contrast media; however, a single dose of nitrendipine 10–20 mg 1 hour before the administration of contrast media offered no benefit.[138,139]

Although dopamine is a nonselective dopaminergic agonist at low doses (2–2.5 mcg/kg/min), it selectively activates the D-1 receptor, thus promoting dilation of the renal arteries and increasing renal blood flow. Investigation of this agent for prevention of contrast media-induced nephrotoxicity has yielded conflicting results, and therefore the use of prophylactic low-dose dopamine is not recommended.[43,137,140] Fenoldopam is a newer, selective D-1 agonist.[57] A study in dogs showed that fenoldopam administered via the renal artery before a high-osmolality contrast media (diatrizoate) prevented decreases in renal blood flow and glomerular filtration rate.[56] In small studies and retrospective analyses in humans, fenoldopam administered at 0.1 mcg/kg/min 1–2 hours before the administration of contrast media and up to 4 hours after has been shown to reduce the incidence of contrast media-induced nephrotoxicity.[117,141,142] However, these data need to be confirmed by a large, controlled trial and pharmacoeconomic factors need to be evaluated before fenoldopam's role in the prophylaxis of contrast media-induced nephrotoxicity can be defined.

When patients at relatively low risk for contrast media-induced nephrotoxicity were given *N*-acetylcysteine (NAC) 600 mg orally twice daily on the day before and the day of contrast media administration, only 2% had nephrotoxicity (defined as a 0.5 mg/dL increase in serum creatinine concentration within 48 hours of the administration of contrast media), as compared to 21% in a control group.[143] The same benefit has not been confirmed by other studies, however, and one study in which NAC was given to high-risk patients who received contrast media for coronary angiography failed to show a decreased risk of nephrotoxicity.[144-146]

Prophylactic intermittent hemodialysis after the administration of contrast media has not been shown to reduce the incidence of nephrotoxicity.[57] However, two studies that investigated the role of prophylactic continuous venovenous hemofiltration (CVVH) versus intravenous hydration in patients with a baseline serum creatinine concentration of >2 mg/dL found a significantly lower incidence of AKI in the CVVH group.[145,146] When performed after exposure to contrast media, 6-hour CVVH was able to remove an amount of contrast media similar to that removed by the kidneys in 12 hours.[172] These data should be interpreted cautiously, however, because hemofiltration itself affects serum creatinine concentrations. Nevertheless, CVVH was associated with lower in-hospital mortality (2% versus 14%).

Sodium bicarbonate alkalinizes the urine and has been shown to inhibit free radical formation in animal models. In a prospective, randomized trial to study the effectiveness of sodium bicarbonate in preventing contrast media induced nephrotoxicity, patients received either intravenous normal saline or sodium bicarbonate. Eight patients in the normal saline group had contrast media-induced nephrotoxicity versus only one patient in the sodium bicarbonate group (p = 0.02).[57]

HMG-CoA reductase inhibitors (statins) may be beneficial in statin-naïve patients undergoing coronary angiography given their pleiotropic properties. A meta-analysis of 13 randomized controlled trials demonstrated that pretreatment with high-dose statin therapy in combination with a hydration protocol reduced the risk of contrast-induced AKI by 53% compared to placebo. Several studies included in this analysis used concomitant prophylactic measures such as NAC or sodium bicarbonate.[147]

Clinical applicability of the data regarding prevention of contrast-induced AKI is hindered by study design limitations such as enrolling too few subjects, using surrogate and inconsistent primary endpoints, and including low-risk patients. These key methodological issues informed the design of the Prevention of Serious Adverse Events following Angiography trial, an ongoing randomized prospective study comparing the effectiveness of sodium bicarbonate, sodium chloride, and NAC.[148]

CISPLATIN

Cisplatin-induced nephrotoxicity is best prevented by dose reduction and aggressive hydration.[35] Infusion of 1–4 L of normal saline within 24 hours of cisplatin therapy is recommended to maintain urine flow rates of 125 mL/hr.[58] Hypertonic saline has also been used to increase chloride concentrations and reduce conversion of cisplatin to reactive platinum species.[59] The use of hypertonic saline (3%) as a vehicle for cisplatin doses >100 mg/m^2 may reduce nephrotoxicity.[58] Hypertonic saline must be used very cautiously in patients at risk for adverse effects, including those with underlying heart failure. Mannitol has been used to enhance dilution of drug within the tubules; however, some clinical trials have found no benefit.[58] The protective effect of furosemide is controversial because of the prerenal effects of diuretics. However, loop diuretics are frequently administered to maintain adequate diuresis in patients at risk for heart failure secondary to hydration.[58] Amifostine is a prodrug that is metabolized to a sulfhydryl donor and can reduce kidney toxicities related to cisplatin therapy. Amifostine should be administered before the initiation of cisplatin therapy to patients at high risk for drug-induced nephrotoxicity. Doses of amifostine ranging from 710 mg to 1,000 mg administered 15 minutes before cisplatin have been shown to significantly reduce nephrotoxicity.[58,60]

MANAGEMENT

Clinicians should consider discontinuing aminoglycosides and using an alternative agent, if possible, when a decline in kidney function occurs during therapy. Spontaneous recovery of kidney function usually occurs within a few days after drug discontinuation.[28] If kidney function does not improve, other causes of nephrotoxicity should be considered. In situations in which aminoglycoside therapy cannot be discontinued, aminoglycoside doses may be continued with a reported recovery of kidney function in some patients.[149-151] A review of six patients with gram-negative osteomyelitis managed with gentamicin for 5–7 weeks demonstrated that aminoglycoside-induced nephrotoxicity occurred with a peak rise in serum creatinine concentration and stabilization of values after approximately 30 days of treatment. Continuation of gentamicin therapy after individualized adjustment of the dosing interval to yield targeted trough concentrations of <2 mcg/ml did not cause additional increases in serum creatinine concentration and was associated with a 50% reduction in serum creatinine concentration in three of the cases.[151]

Amphotericin B should be discontinued in patients in whom nephrotoxicity develops, and therapy with an alternative antifungal agent or a lipid-based product initiated. Substitution of a lipid-based amphotericin B product has resulted in improved kidney function in patients in whom amphotericin B-induced nephrotoxicity developed.[37]

Patients with contrast media-induced nephrotoxicity should receive supportive care. Adequate hydration with 0.45% saline solution and the avoidance of other nephrotoxins may help hasten kidney recovery.[41] Infusion rates of intravenous fluids should be titrated to maintain positive fluid balance and high urine output.[50]

Management of AKI secondary to cisplatin therapy is typically supportive and should include aggressive hydration. Electrolyte wasting, especially the loss of magnesium, is a frequent manifestation of cisplatin-induced AKI. Supplementation with intravenous magnesium (0.5 mEq/kg/day given as a continuous infusion) is indicated in patients with serum magnesium concentrations <1 mEq/mL to prevent adverse neurologic and cardiac effects.[58] Patients with serum magnesium concentrations >1 mEq/L can be treated with oral magnesium oxide. Hypokalemia and hypocalcemia can also occur and may be refractory to treatment if hypomagnesemia is not corrected.

INFORMATION FOR PATIENTS

Patients scheduled for elective procedures requiring iodinated contrast media should be counseled regarding the possibility of acute kidney dysfunction, especially if they are diabetic and have pre-existing kidney disease. Patients and providers should be advised to hold medications that affect renal hemodynamics. Patients should be counseled regarding the potential risk of AKI with cisplatin therapy and should be advised of the preventive measures required (e.g., hydration and amifostine, if indicated) to minimize the risk of chemotherapy-related kidney problems. Kidney function should be evaluated after completion of the chemotherapy cycles, and patients should be advised to notify their healthcare provider if they notice symptoms of frequent urination, low serum magnesium (muscle weakness, tremors, agitation, confusion, fainting), low serum calcium (muscle twitching, paresthesia), or low serum potassium (muscle weakness or cramps).

ACUTE INTERSTITIAL NEPHRITIS

Acute interstitial nephritis (AIN) is most commonly caused by hypersensitivity to a drug that results in infiltration of the tubulointerstitium by inflammatory cells, including T cells, monocytes, and eosinophils.

CAUSATIVE AGENTS

The agents most frequently associated with AIN are antibiotics and NSAIDs.[1,61] Methicillin, rifampin, and fenoprofen are among the agents most frequently implicated.[150] Table 41-1 lists other causative agents.

EPIDEMIOLOGY

AIN is a relatively rare complication of drug therapy. AIN attributed to various causes, including drugs, was present in 2–3% of biopsies reviewed in two case series.[61,62] AIN is associated with many classes of drugs but the incidence can be higher for some agents within a given class.[63] For example, β-lactams are known to be associated with AIN; however, methicillin was found to be associated with a much higher incidence than other β-lactams, resulting in its removal from the U.S. market. The reason for the increased incidence is not clear but may be due to haptenic dimethoxyphenylpenicilloyl groups.

MECHANISMS

AIN is a hypersensitivity reaction with kidney manifestations. There are four principal mechanisms by which drugs may induce AIN: (1) the drug binds to the tubular basement membrane, acting as a hapten; (2) the drug may be structurally similar to an antigen that is normally present in the tubular basement membrane resulting in inappropriate immune complex formation; (3) the drug may bind to the tubular basement membrane itself, inducing an antibody response; and (4) the drug may elicit an antibody response and circulating immune complexes may deposit in the tubular interstitium.[63,149]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Although the rise in serum creatinine and blood urea nitrogen concentrations associated with AIN may not occur for several weeks after a patient's initial exposure to a causative agent, increases may be seen within 3–5 days of a second exposure.[149] Systemic manifestations of hypersensitivity may be present, including low-grade fever (30–50%), maculopapular rash (33–50%), and eosinophilia (16–33%).[61-63,152,153] Urinalysis may reveal eosinophiluria (40–90%), hematuria (48–60%), proteinuria (16–60%), or pyuria (50–53%).[61-64,152,153] The only definitive diagnostic test for AIN is kidney biopsy, which typically reveals patchy or diffuse inflammatory infiltrates consisting predominantly of lymphocytes and plasma cells within the interstitium.[63,64,149] However, biopsies are not frequently performed unless the injury does not resolve after the offending drug is discontinued.

Differential diagnosis includes other potential causes of intrinsic kidney injury including nondrug-related AIN and glomerulonephritis if large amounts of protein are present in the urine.

RISK FACTORS

AIN is idiopathic and there are no well-established risk factors. AIN is not dose-related.[149] Previous exposure to some agents such as rifampin has been associated with the development of AIN on subsequent exposure.[150]

MORBIDITY AND MORTALITY

AIN is frequently reversible when the suspect drug is identified and discontinued.[63,149] Dialysis may be required temporarily if kidney recovery is slow and the patient has clinical signs of uremia, emergent hyperkalemia (serum concentration >6 mEq/L or electrocardiographic changes), or volume overload.[153] In cases of progressive AIN (involving a majority of the interstitium), kidney function may not return to baseline. The prognosis is worse when diffuse versus patchy infiltrates are found on kidney biopsy. AIN that persists for >3 weeks is also associated with a poor prognosis.[154] Approximately 33% of patients require short-term dialysis.[63]

PREVENTION

AIN is rare, and there are no known predictors of the disease. In general, a patient should not be re-challenged with a drug that has caused AIN or another drug from the same class of agents. The occurrence of drug-induced AIN should be carefully documented in the patient’s medical record to help prevent future exposures.

MANAGEMENT

The primary management of AIN involves discontinuation of the suspect drug or drugs.[152] Although administration of corticosteroids is sometimes recommended, there have been no controlled studies to determine the benefit of this intervention. Doses of 1 mg/kg/day of prednisolone or prednisone given orally for 1 week have been used with or without intravenous methylprednisolone pulses; however, this treatment has not been shown to correlate well with resolution of AIN.[61,64,155,156]

INFORMATION FOR PATIENTS

Patients should be advised to consult with their healthcare provider if fever, rash, edema, or reduced urine output develops while taking an agent known to cause AIN. Patients who have a history of AIN should be cautioned to avoid future exposure to the causative agent or drugs within the same class.

NEPHROLITHIASIS

Nephrolithiasis is most commonly caused by precipitation of drug crystals in the ureter, resulting in obstruction of urine flow.[157,158]

CAUSATIVE AGENTS

Table 41-1 lists the drugs most frequently reported to cause nephrolithiasis. The drugs most commonly associated with this disorder have acidic pKa values (e.g., sulfadiazine, pKa = 6.5) and are more likely to supersaturate at acidic urinary pH (normal urine pH ranges from 4.5 to 7.8).

EPIDEMIOLOGY

Although approximately 3–5% of people experience nephrolithiasis, drug-induced nephrolithiasis is a rare condition, accounting for only 0.8–2.5% of all cases.[159,160]

MECHANISMS

Crystal formation occurs due to supersaturation of the urine with solute, resulting in the formation of calculi or stones in the ureter.[159] Depending on the salt form of the drug, crystal formation is enhanced under either alkaline or acidic conditions.[159] Indinavir (pKa 6.2), for example, is more soluble at an acidic pH and stone formation and the risk of nephrolithiasis may increase when the urine pH is above 5.[157] pKa of other agents associated with nephrolithiasis are as follows: acyclovir (9.25), allopurinol (7.83), foscarnet (7.27), furosemide (7.5), topiramate (8.6), and zonisamide (10.2). Drugs that increase urinary calcium or uric acid may enhance the risk of stone formation.[161]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The majority of patients with nephrolithiasis present with renal colic resulting from crystals lodging in the ureter.[157] The hallmark is severe flank pain unrelieved by change in position.[157] Other symptoms may include pain radiating to the groin, fever, and nausea and vomiting.[157,161] Nonspecific findings on urinalysis may include the presence of red or white cells and fractional excretion of sodium >1%. If the stone is passed, it can frequently be identified by microscopic examination, and further examination with techniques such as x-ray diffractometry and infrared spectroscopy is sometimes carried out. Drugs can produce crystals with characteristic structure. Indinavir, for example, produces crystals that appear as tangled rods and needle-shaped crystals within a protein matrix.[161] Conditions to consider in the differential diagnosis of drug-induced nephrolithiasis include abdominal aortic aneurysm, appendicitis, ectopic pregnancy, pyelonephritis and nephrolithiasis secondary to calcium oxalate or uric acid crystal formation. Definitive diagnosis of drug-induced nephrolithiasis is made by intravenous pyelography or ultrasound and microscopic examination of the passed stone.[157,161]

RISK FACTORS

Decreased fluid intake is a potential risk factor for drug-induced nephrolithiasis as it can increase stasis in the ureter. Longer duration of therapy with drugs known to cause nephrolithiasis may be associated with an increased risk of stone formation. In addition, the risk of nephrolithiasis appears to increase with increasing doses of drugs such as felbamate and indinavir.[78,157]

PREVENTION

Increasing urine flow rates may decrease the risk of crystallization. Increasing the urine output to 150 mL/hr by increasing fluid intake for 3 hours after an oral dose of indinavir has been recommended.[157]

MANAGEMENT

Management of nephrolithiasis and renal colic should include aggressive diuresis to encourage spontaneous passage of the stone and pain management, most commonly with narcotic analgesics or ketorolac.[79,157] Meperidine and morphine should not be used for pain management if significant kidney impairment is present and an extended duration of therapy (>3 days) is expected. Both agents have renally excreted metabolites that are associated with adverse neurologic (meperidine) and central nervous system (morphine) effects in the presence of kidney dysfunction. If the stone is passed spontaneously, it should be sent for analysis to confirm the diagnosis.

INFORMATION FOR PATIENTS

Patients who have been prescribed drugs known to cause nephrolithiasis should be advised to maintain adequate fluid intake, especially after drug administration, and to notify a healthcare professional if they have symptoms of renal colic.

GLOMERULONEPHRITIS

Drug-induced glomerulonephritis is immune-mediated and causes damage to the glomerular basement membrane. This damage compromises filtration and increases permeability, allowing protein to pass into the urine.[162]

CAUSATIVE AGENTS

Table 41-1 lists the drugs reported to cause glomerulonephritis. These drugs are diverse in their structure and pharmacology; however, all can cause immune-mediated damage to the glomerulus.

EPIDEMIOLOGY

Drug-induced glomerulonephritis is a rare complication of drug therapy, and most of the available data regarding its occurrence come from published case reports. Although a number of agents have been implicated, the disease is most frequently associated with NSAIDs.

MECHANISMS

Drug-induced glomerulonephritis is typically immune-mediated. Similar to the pathogenic mechanisms in AIN, the causative drugs may act as haptens, result in immune complex formation, or stimulate production of autoantibodies against glomerular structures.[162] Drug-induced glomerular damage can also occur because of acute vasculitis, in which glomerular capillaries are damaged by inflammatory reactions to circulating immune complexes.[68]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Drug-induced glomerulonephritis typically presents as nephrotic syndrome, which is defined as proteinuria >3.5 g/day. Other clinical manifestations may include reduced urine output and edema of the lower extremities and possibly the face.

When drug-induced glomerulonephritis is associated with a severe hypersensitivity reaction, fever, rash, and eosinophilia may also be present.[68] Definitive diagnosis is made by kidney biopsy, and three associated lesions have been identified: membranous nephropathy, minimal-change nephropathy, and focal segmental glomerulosclerosis.[68,163] Glomerular injury from drug therapy is relatievely rare compared to other etiologies of drug-induced kidney injury. A consensus report sought to define a phenotype for glomerular disorders. Because of the low incidence and overlap with other kidney injury diagnoses, one of the primary criteria for the phenotype was biopsy-proven drug-induced glomerular disease. The consensus report further indicates that the biopsy should be done while the patient is receiving the drug or within 4 weeks of stopping.[170]

Membranous nephropathy is the most common lesion that occurs in patients with drug-induced glomerulonephritis.[162] It is characterized by immune complex deposition in the glomerular basement membrane. The membranous deposits are more widely spaced and focally distributed in patients with drug-induced disease than those in idiopathic membranous nephropathy.[162] Drugs most commonly associated with membranous drug-induced glomerulonephritis include NSAIDs, gold, and penicillamine.[83,162] Because of the idiopathic nature of drug-induced glomerulonephritis, time to onset is not well-documented for most drugs. A review of the literature focused on NSAID-induced membranous nephropathy reported a median onset of 43 weeks after initiation with a range of 4 weeks to 3 years.[168]

In patients with minimal-change nephropathy, glomeruli appear normal and no deposits are visible with immunofluorescence microscopy or electron microscopy; however, patients typically have nephrotic-range proteinuria. Minimal-change nephropathy is commonly associated with AIN and has been reported to occur with NSAIDs, rifampin, phenytoin, and ampicillin.[162]

Focal segmental glomerulosclerosis is characterized by areas of sclerosis in <50% of the glomeruli. This lesion is commonly associated with heroin abuse and has also been reported with lithium therapy.[164]

RISK FACTORS

Drug-induced glomerulonephritis is idiopathic, and there are no well-established risk factors. The presence of the human leukocyte antigens DR3 and B8 appear to be associated with increased susceptibility to gold-induced glomerulonephritis.[162] A review of reports of NSAID-induced glomerulonephritis identified an association between duration of therapy and the severity of the glomerular lesion.[68] Patients with minimal-change disease were more likely to have an underlying rheumatologic disease. The risk for drug-induced glomerulonephritis has not been associated with drug dose.

MORBIDITY AND MORTALITY

Drug-induced glomerulonephritis typically resolves after discontinuation of the causative agent. Follow-up evaluation of 72 patients with NSAID-induced glomerulonephritis found that 68 who had discontinued NSAIDs had improved kidney function, with 57 returning to their baseline kidney function.[68] A renal biopsy is typically not performed unless proteinuria and kidney function fail to improve after stopping the drug.

PREVENTION

Drug-induced glomerulonephritis is rare and idiopathic, and there is little information available regarding risk factors or prevention. Gold therapy should be avoided in patients with human leukocyte antigens DR3 or B8.

MANAGEMENT

The primary management strategy for drug-induced glomerulonephritis is discontinuation of the suspected causative agent. Corticosteroids may be initiated in severe cases; however, the value of this treatment has not been demonstrated conclusively. The dose of corticosteroid is not well established; traditional aggressive regimens used for nondrug-related glomerulonephritis can be used (e.g., 1 g of methylprednisolone) or a more conservative approach similar to doses used in AIN can be initiated.[169] Diuretics may be required to manage severe edema. Dialysis is indicated only if the patient has kidney insufficiency associated with clinical signs of uremia or hyperkalemia that does not respond to other treatment.

INFORMATION FOR PATIENTS

Patients receiving drugs known to cause glomerulonephritis should be advised to consult their healthcare provider if they develop fever, rash, edema, or reduced urine output. If the patient has a history of drug-induced glomerulonephritis, he or she should be cautioned to avoid future therapy with the causative agent or related drugs.
